Magnesium-lithium (Mg-Li) alloys are among the lightest structural materials. Although considerable work has been done on the Mg-Li system, little is known regarding potential ordered phases. A first and rapid analysis of the system with the high-throughput method reveals an unexpected wealth of potentially stable low-temperature phases. Subsequent cluster expansions constructed for bcc and hcp superstructures extend the analysis and verify our high-throughput results. Of particular interest are those structures with greater than 13 at. % lithium, as they exhibit either partial or complete formation as a cubic structure. Order-disorder transition temperatures are predicted by Monte Carlo simulations to be in the range 200–500 K.

DOI: 10.1103/PhysRevB.81.024112 PACS number(s): 61.50.Ks, 81.30.Hd

I. MOTIVATION AND BACKGROUND

Emerging technologies increasingly depend on the production of ultralight-weight materials. Magnesium-lithium (Mg-Li) alloys are the lightest metallic alloys, having densities near that of plastics,1–3 and are strong enough to be used in a variety of high-performance applications. In particular, Mg-Li alloys are good candidates for material applications in industries such as aerospace and automotive manufacturing.4

As an alloying agent in magnesium, lithium is advantageous principally because of its low density and cubic crystal structure. The addition of lithium converts the hexagonal-close-packed (hcp) structure of natural magnesium to a more ductile and formable body-centered-cubic (bcc) alloy. Addition of 13 at. % Li partially converts the alloy to a cubic structure and content exceeding 33 at. % results in total conversion.5

Although the Mg-Li system has been studied extensively,6–11 evidence suggesting the formation of ordered phases is notably sparse. Diffusionless transformations of the martensitic type have been observed in pure Li, and similar transformations occur in low-temperature magnesium alloyed lithium at certain concentrations.11,12 Binary ordered phases have not been conclusively identified, however, and any instances contained in the literature are indeterminate.6,9,13,14

The results of high-throughput (HT) ab initio calculations performed with the AFLLOW package (described later) show, however, that the heat of formation is negative for a large number of potential structure types, implying the existence of at least one thermodynamically stable ordered phase (Fig. 1).

II. FIRST-PRINCIPLES METHOD

Following the HT results, we have made predictions of Mg-Li ordered phases using the cluster-expansion (CE) method—a first-principles-based approach in which input data is mapped to a truncated Ising-type Hamiltonian. The configurational Hamiltonian allows for a fast ground-state search (GSS) over many derivative superstructures.16 The CE method was applied to the Mg and Li lattice configurations (bcc and hcp, respectively). Although minimum-energy configurations may exist outside those considered, superstructures derived from the parent lattices of the alloy constituents generally include the lowest-energy configurations. This assumption is particularly supported for Mg-Li by the existence of bcc derivative superstructures exclusively as ground states in the HT results and by phases present in experimental phase diagrams (Fig. 2).

FIG. 1. High-throughput formation enthalpy calculations for Mg-Li. Structures resting on the convex hull are labeled according to their Strukturbericht designation and are displayed prominently. Note that many computed structures have negative formation enthalpy, suggesting an ordering system. MoTi\textsuperscript{C11b} prototype from Ref. 15.
Quantum-mechanical energies used for the HT and CE approaches were computed using density-functional theory (DFT) as implemented by the Vienna ab initio simulation package (VASP) software. Following the method of Froyen, so-called “equivalent points” were used to form the k-point mesh, resulting in reduced systematic error in the calculation of formation enthalpy. Perdew-Burke-Ernzerhof projector-augmented wave pseudopotentials with semicore s and p states treated as valence were used. The plane-wave energy cutoff was approximately 339 eV. Energies were calculated at zero temperature and pressure without spin polarization, zero-point motion, or lattice vibrations. All crystalline structures were fully relaxed (cell volume and shape and the basis-atom coordinates inside the cell). Numerical convergence to about 1 meV/atom was ensured by the high-energy cutoff and by dense k-point meshes.

In the HT work, the calculations were performed using the high-throughput framework AFLLOW. For each system, the energies of 204 crystal structures were calculated. In addition to the 176 configurations described in Ref. 15, these included all the symmetrically distinct hcp-based, bcc-based, and fcc-based superstructures with up to four atoms per cell and additional prototypes. The additional prototypes were considered because they are common or related to Mg alloys. This protocol gives reasonable results. In Ref. 15, it was shown that the probability of reproducing the correct ground state, if well defined and not ambiguous, is \( \eta^* \sim 96.7\% \) (“reliability of the method.” Eq. (3)). For the HT approach, we did not consider lattice superstructures with more than four atoms per cell due to the fact that their number increases exponentially. Therefore, even if it is impossible to rule out the existence of an undetected ground state, the protocol is expected to give a reasonable balance between high-throughput speed and scientific accuracy to determine miscibility of Mg-Li alloys.

III. CLUSTER-EXPANSION METHOD AND GROUND-STATE SEARCH RESULTS

In the CE formalism, atomic configuration is defined by first associating a set of “spin” values to atomic type. The configurational properties of a structure are then captured by the averages of spin products or values of correlation functions on the lattice.

The correlation functions, evaluated over each symmetrically unique “cluster,” form a mathematically complete basis for a lattice of size \( N \) by which any configurational property may be expanded. A set of constants termed effective cluster interactions (ECIs) form the coefficients of the expansion by which the material property in question is expressed.

The utility of the CE method is that a physical quantity such as energy may be expanded entirely in configuration space. This allows for exhaustive searches over configurational domains in order, for example, to find minima. Given cluster-expanded formation enthalpy, minimum-energy structures serve as strong candidates for thermodynamically stable ordered states. In the case of a binary system, the CE expresses the energy of a lattice configuration \( \sigma \) as

\[
E_{CE}(\sigma) = J_0 + \sum_f N_f \sum_1 \Pi_f(\sigma)J_f,
\]

where \( \sigma \) defines the occupation of \( N \) lattice sites by A and B atoms, \( J_f \) is the ECI for cluster \( f \), \( N_f \) is the number of clusters of type \( f \), and \( \Pi_f \) are the averaged spin \(( \pm 1 \) for binary systems) products for cluster \( f \) in configuration \( \sigma \).

Effective cluster interactions were found using least-squares regression and a genetic algorithm. The method we employed involved two general steps as implemented in the universal cluster-expansion software package. The method of cross validation score, in units of energy, should be a

\[
S_{CV} = \frac{1}{n} \sum_{i=1}^{n} |E_{CE}(\sigma_a) - E_{DFT}(\sigma_a)|.
\]

The cross validation score, in units of energy, should be a small fraction of the energies of input structures so that reliable results are obtained. Typical fitting errors for the Mg-Li system were between 0 and 3 meV/atom. With input energies near –30 meV/atom, the errors were in the reasonable range. A total of 83 and 73 structures comprised the input data set used in the construction of bcc and hcp CEs, respectively.

Once a CE was constructed, a ground-state search was performed over large numbers of derivative superstructures (see Fig. 3). Thermodynamically stable ground states, how-
ever, are not necessarily the minimum-energy configurations at each concentration. One usually encounters a concentration in which the average energy of two structures with neighboring concentrations yields a mixed phase with lower total energy. The tie lines connecting all pairs of minimum-energy structures were thus determined. When the structure in question rests below all such tie lines it was included as a ground state. The complete set of structures determined in this manner comprises the minimal convex set of structures (the convex hull). Figure 3 includes the convex hulls for the bcc and hcp Mg-Li CE constructed using the predicted energies from fits generated using 83 and 73 input structures, respectively.

The absolute minima within the set of configurations that included both bcc and hcp superstructures were found by scaling hcp structure formation enthalpy by the difference in free energy of pure Mg and Li according to concentration. The free energy was computed for hcp Mg and Li and bcc Mg and Li, and the formation enthalpy of hcp structures were adjusted in the following manner:

$$ H \rightarrow H + [x \Delta H_{\text{Mg}} + (1-x) \Delta H_{\text{Li}}]. $$

Here $H$ is the formation enthalpy of a ground-state structure, $x$ is the concentration of Mg, and $\Delta H_{\text{Mg}}$ and $\Delta H_{\text{Li}}$ are the differences in the hcp and bcc free energies of Mg and Li. CE-predicted energies shown in Fig. 3 scaled relative to one another in this fashion are shown in Fig. 4.

In the case of bcc Mg-Li, the convex-hull-constructed using DFT energies of CE-predicted ground states reveal ground states $C11_\text{p}$, B2, and $L6_0$ (see the Appendix for details of the method used). These structure types are in agreement with the HT results and are referred to by their Strukturbericht designation. It is perhaps of interest to note that the ground-state structures are several millielectron volt lower than the structure nearest in energy with the same concentration except at 50% (B2). In the case of B2, the energy is found to be only slightly lower than an $A2B_2$ structure with [011] directed stacking planes (similar to the NbP face-centered-cubic superstructure) (Fig. 5). A slight difference in formation enthalpy is evidently the reason many CEs were unable to accurately predict the relative energies of this NbP-like structure (corresponding to structure 19 in Table I) and the true ground state, B2.

Mg-Li ground-state predictions on the hcp lattice were treated in the same manner as the bcc structures, i.e., VASP was used to directly compute their energies from which the ground states were determined. Ground states were found at concentrations $x = 1/8, 1/2, 2/3$, and $3/4$ Mg. In this case, the configurations do not correspond to known structures. Hcp phases were higher in energy than the bcc ground states across the concentration range excluding pure Mg (see Fig. 6). From the superposed energies of bcc and hcp Mg-Li, it can be seen that the two-phase region that extends from approximately 17 at. % Li at finite temperatures broadens as the temperature is lowered and the solubility of Mg in Li decreases.
IV. ORDER-DISORDER TRANSITIONS PREDICTED BY MONTE CARLO SIMULATION

Complex Ising-type Hamiltonians with many couplings are notoriously difficult to extend to finite temperatures with Monte Carlo (MC) methods, especially in the low-temperature region. Numerical problems also arise when one attempts to model the system around the critical temperature (i.e., due to critical slowing). In general, the behavior of systems containing many interactions is not well understood and MC convergence times often make the task of modeling the system nearly intractable.

The CEs we constructed for Mg-Li utilized large numbers of figures in order to provide accurate energy predictions across the concentration range. As a result, however, Monte Carlo simulations involving these complex Hamiltonians present significant numerical difficulties. If determining the critical temperature is to be computationally feasible, it is necessary to simplify the complex CE to one that involves fewer interactions.

The CEs we constructed for Mg-Li utilized large numbers of figures in order to provide accurate energy predictions across the concentration range. As a result, however, Monte Carlo simulations involving these complex Hamiltonians present significant numerical difficulties. If determining the critical temperature is to be computationally feasible, it is necessary to simplify the complex CE to one that involves fewer interactions.

Although the simplified CE is certainly incapable of predicting the behavior of ordering as accurately as one containing many figures, by ensuring the proper ground states and energies are predicted, sufficiently accurate conclusions may be made. Further, rather than a detailed study of the nature of the transition, it was our primary interest to determine generally where the order-disorder transitions occur in order to guide experimental attempts to realize the ordered phases.

For the above reasons, a five-term CE on the bcc lattice was constructed for the purposes of conducting finite-temperature MC simulations. The statistical analysis conducted on many CEs provided the criteria by which we were able to narrow the selection of between many five-term CEs. Specifically it was required that the five-term CE-predicted ground states at 1/3, 1/2, and 2/3 magnesium with structure types, C11b, B2, and C11b, respectively, and that predicted energies were comparable to those computed using first-principles methods. In the five-term CE, predicted energies differed from DFT calculations on average less than 5 meV, roughly an order of magnitude smaller than input energies.

Canonical Monte Carlo simulations were performed using the five-term CE on a 30×30×30 bcc lattice with periodic boundary conditions. Equilibration times were between 5×10^6 and 15×10^6 MC steps. The temperature was decreased uniformly in decrements of 10 K initially from 2000 to 50 K. Transitions were identified by calculating the specific heat, using the usual statistical relation involving the mean-square deviation of the energy from the mean value.
Figure 7 displays the configurational specific heat of the three predicted ordered phases. Transition temperatures were estimated by identifying the “divergence” in the heat capacity; the structure types C11b exhibit transitions at approximately 190 and 210 K for 1/3 and 2/3 Mg, respectively. Simulations at 50%, B2, exhibited more resistance to equilibration and required many more flips per MC time. Nevertheless, the transition was identified to be between 300 and 450 K by pair-correlation values. Comparison of pair-correlation values of the MC cell with the CE-predicted ground-state structures reveals good agreement after the transition. At 50% the correlation values approach those of the expected B2 structure gradually over the temperature region shown (Fig. 7), suggesting that although the system was not fully equilibrated an order-disorder transition had occurred.

The range of transition temperatures predicted by the MC simulations is generally supported by the results of sonic measurements for low-temperature Mg-Li alloys. In the work of Barrett and Trautz, the onset of spontaneous structural transitions were measured by recording audible clicks, the result of the rapid shearing motions that accompany the transition. For materials containing a large percentage of Mg content, few audible clicks were heard, and the specific nature of the partial ordering was not identifiable by diffraction techniques. However, the onset of spontaneous ordering for alloys containing greater than 20 at. % Mg were determined by noting the temperature at which the first clicks were heard and was estimated between 140 and 200 K.

V. CONCLUSION

In conclusion, the CE method predicts bcc ordered phases at several concentrations including one which may be well suited for structural applications, C11b. With the exception of pure Mg, hcp phases were found to be higher in energy than bcc ground states across the concentration range. Order-disorder transition temperatures, predicted by MC simulations, have been reported for the three bcc ordered structures between 200 and 400 K.

The predicted low-temperature transitions of the Mg-Li bcc ordered phases possibly explain why they have evaded experimental observation despite a relatively large amount of investigation in the system. Additionally, developing methods to experimentally realize the Mg-Li ordered phases is likely to require significant effort due, in particular, to the low temperatures of the transitions and possible kinetic limitations.

However, the bulk low-temperature phases should not be ruled out, even at high temperature. Size-induced stabilization present at the nanoscale may promote stability at higher temperature for nanodispersed precipitates. Although the mechanical properties would not modify the solid-solution Mg-Li appreciably, the overall effect in thermal and electric transport can be dramatic, as it has been shown for nanoprecipitates in semiconducting materials. Thus, the enhanced structural properties of alloys containing even small amounts of ordering provide a significant incentive in this regard. Furthermore, low-temperature ordering has the inherent advantage of increased stability at higher temperatures possibly allowing for practical application of the ordered alloys if initially realized.

APPENDIX

The genetic algorithm and leave one out cross validation provide a useful framework for constructing a CE that accurately fits input data; furthermore, a CE produced in this manner is capable of predicting the energy of structures not included in the input set provided that the “physics” of the input data is representative of the entire system (although off-lattice structures are not included in the configuration space, HT and experimental data suggest that additional structures will not form in Mg-Li. Not only are the HT energies higher than both hcp and bcc CE-predicted structure energies but the majority of HT ground-state predictions are bcc superstructures.)

By adding structures in underfit regions to the input structure set, the overall predictive capacity of the CE was improved. Low-energy structures without similar input structures as well as additional structures similar in configuration to poorly predicted input structures were added to the input set. Structures were added in this manner by comparing successive fits so that the final input data set was determined to ensure a broadly accurate parameterization of configuration space. A total of 85 bcc-derived and 71 hcp-derived superstructures were ultimately used in the construction of the CEs.

The utility of the iterative process hints at the underlying physical workings of the CE method. Input structures contribute to the CE via the addition of physics yet unaccounted for. Iteratively adding structures from regions of poorly fit data, and from regions lacking input data, will then, in principle, lead to a CE capable of making accurate predictions across configuration space. Furthermore, given a set if interaction terms representative of the system, the inclusion of additional input data should do little to alter the ground-state predictions of the CE constructed using these figures.

The durability of the fit, i.e., the immutability of ground-state predictions with the inclusion of new input data, was studied in the following manner. A database containing the complete set of input structures was parsed into input sets of increasing size; this was done several times with unique parsing, and a CE was constructed for each input set. Ground-state predictions made by the CEs were compared for agreement, and frequently predicted ground-state concentrations formed a group of credible predictions.

For bcc Mg-Li, a database containing the formation enthalpies of 85 input structures were parsed into 39 groups of input structures five times. CEs were constructed for each of the 39 groups yielding 39 predictions of the Mg-Li ground states. The structures and associated concentrations predicted by fits containing the entirety of the input data (A–E) are listed in Table I. The frequencies of prediction of ground states at each listed concentration are shown in the second

TABLE II. Hcp Mg-Li ground-state predictions as in Table I. Several frequent predictions are not affirmed by full fits and thus additional concentrations have been included.
column. It is seen that the predictions made by CEs constructed using the entire input set generally correspond to predictions made by the majority of fits.

The hcp Mg-Li system was treated similarly. Input data computed for 71 input structures was parsed into 33 unique input sets five times. In contrast to the bcc case, however, several concentrations not predicted by CEs constructed using the complete input data were found to have a high frequency of prediction by the totality of fits. Thus, these are also included in the table (Table II).

The potential ground-state pool was significantly reduced by comparing the predictions of many CEs. However, because the precision necessary to distinguish small differences in structure energetics are not to be expected from the finite CE, DFT was used to directly compare the energies of the final group of candidates. VASP was used to evaluate each of the candidate structures listed in Tables I and II as well as candidate structures not necessarily predicted by fits A–E but with significant frequency of occurrence.
(2008).
