Fossil records reveal dramatic shifts in woody species’ distributions during the late Pleistocene through the recent Holocene in the American Southwest (Van Devender and Spaulding 1979, Spaulding and Graumlich 1986, Betancourt et al. 1990, Miller and Wigand 1994). One such migration involves the southward retreat of *Quercus turbinella* Greene, an evergreen diffuse-porous oak, from northern Utah. This species hybridizes with *Quercus gambelii* Nutt., a deciduous ring-porous oak, in contact zones in southwestern Utah and northwestern Arizona (Cottam et al. 1959). Relict hybrid clones occur in northern Utah along the western front of the Wasatch Mountain Range almost 400 km north of the current contact zone (Fig. 1). Cottam et al. (1959) argued that hypsithermal warming was responsible for the northward migration of both species through the Arizona-Utah region, and more recent cooling has resulted in extirpation of the evergreen *Q. turbinella* from northern Utah, leaving behind the more cold-tolerant hybrid individuals. Neilson and Wullstein (1983, 1985), however, found that successful seedling establishment in both *Q. turbinella* and *Q. gambelii* depends on summer moisture and argued that the northern range limits for both species are controlled synergistically by 2 distinct air mass boundaries: the polar front that controls the probability of late spring frost, and the summer “monsoon” that controls summer moisture availability. Biogeographic implications of seedling stress tolerance and demography, however, do not reveal why hybrid individuals have persisted and

**CARBON ISOTOPE DISCRIMINATION AND WATER RELATIONS OF OAK HYBRID POPULATIONS IN SOUTHWESTERN UTAH**

David G. Williams¹ and James R. Ehleringer²

**ABSTRACT.—**The evergreen oak *Quercus turbinella* and the deciduous *Q. gambelii* form natural hybrids in southwestern Utah and northern Arizona. Hybrid individuals also are found in northern Utah in a region where only *Q. gambelii* currently exists, indicating that *Q. turbinella* has recently retreated southward. Our objectives were to (1) examine the ecophysiology of parental taxa and hybrids under natural conditions in southeastern Utah, and (2) investigate the level of integration between leaf carbon isotope discrimination (a synthetic gas exchange trait) and structural and chemical traits of leaves in morphologically variable hybrid populations. Leaf length, width, mass-to-area ratio (LMA, g m⁻²), and nitrogen concentration (N, g g⁻¹) within 2 hybrid populations near New Harmony, Utah, were highly intercorrelated. Variation within the hybrid populations spanned mean values for these traits observed in parental taxa from adjacent “pure” populations of each species. Carbon isotope discrimination (Δ), an integrated measure of the ratio of intercellular to ambient CO₂ concentration, ranged from 16.1‰ to 19.6‰ within the 2 hybrid populations and was positively correlated with leaf nitrogen concentration and negatively correlated with LMA; individuals in hybrid populations with leaves resembling *Q. gambelii* had the highest leaf Δ and N concentrations and lowest LMA compared with leaves from plants that resembled *Q. turbinella*. CO₂ uptake is limited by stomatal conductance and possibly by mesophyll resistance to a greater extent in *Q. turbinella* phenotypes than in intermediate or *Q. gambelii* phenotypes. δD of stem xylem water (an indication of active rooting depth) and predawn water potential during the peak monsoon period in August were not correlated to leaf Δ values within the hybrid populations. Several individuals that were morphologically similar to *Q. turbinella* in the hybrid populations maintained high predawn water potentials and derived moisture from winter recharge that presumably was taken from deep soil layers. Apparently, a few adult individuals of the *Q. turbinella* phenotype in hybrid populations accessed water from deep in the soil profile, which enabled them to avoid summer drought. Reduced monsoonal activity may have been an important, but not the single, determinant of *Q. turbinella*’s retreat from northern Utah during the recent Holocene.

**Key words:** oak hybrids, *Quercus turbinella*, *Quercus gambelii*, leaf structure, leaf nitrogen, carbon isotope discrimination, δ¹³C, δD, water potential.

Fossil records reveal dramatic shifts in woody species’ distributions during the late Pleistocene through the recent Holocene in the American Southwest (Van Devender and Spaulding 1979, Spaulding and Graumlich 1986, Betancourt et al. 1990, Miller and Wigand 1994). One such migration involves the southward retreat of *Quercus turbinella* Greene, an evergreen diffuse-porous oak, from northern Utah. This species hybridizes with *Quercus gambelii* Nutt., a deciduous ring-porous oak, in contact zones in southwestern Utah and northwestern Arizona (Cottam et al. 1959). Relict hybrid clones occur in northern Utah along the western front of the Wasatch Mountain Range almost 400 km north of the current contact zone (Fig. 1). Cottam et al. (1959) argued that hypsithermal warming was responsible for the northward migration of both species through the Arizona-Utah region, and more recent cooling has resulted in extirpation of the evergreen *Q. turbinella* from northern Utah, leaving behind the more cold-tolerant hybrid individuals. Neilson and Wullstein (1983, 1985), however, found that successful seedling establishment in both *Q. turbinella* and *Q. gambelii* depends on summer moisture and argued that the northern range limits for both species are controlled synergistically by 2 distinct air mass boundaries: the polar front that controls the probability of late spring frost, and the summer “monsoon” that controls summer moisture availability. Biogeographic implications of seedling stress tolerance and demography, however, do not reveal why hybrid individuals have persisted and
adult *Q. turbinella* individuals have disappeared from northern Utah in spite of the fact that clones of these oaks have long life spans.

The present northern limit of *Q. turbinella* is geographically more closely related to the sharp summer moisture gradient in the Southwest than is that of *Q. gambelii*. Ecophysiological studies conducted in natural populations and in common gardens reveal that adult individuals of *Q. gambelii* do not take up summer precipitation but instead use winter moisture stored in deep soil layers during the growing season (Phillips and Ehleringer 1994). Ehleringer and Phillips (1996) demonstrated that adult *Q. turbinella* in a common garden near Salt Lake City, far north of *Q. turbinella*’s present northern boundary, took up water from shallow soil layers following summer rains. The tradeoff associated with having roots deployed in shallow soil layers is that plants experience very low and potentially damaging soil water potentials during the summer months in the absence of significant monsoon storms. Hybrid individuals between these 2 oaks appear to have an intermediate rooting depth that allows them to persist in the summer-dry region of northern Utah, where the intensity of the summer monsoon has apparently declined over the recent Holocene. Greater drought tolerance and higher water-use efficiency are commonly found among species or populations that extract water only from shallow soil layers compared to taxa that have access to a stable water source deep in the soil profile (Knapp and Fahenstock 1990, Flanagan et al. 1992, Williams and Ehleringer 1996). Ehleringer and Phillips (1996) and Ehleringer and Smedly (1988) showed that stomatal conductance is lower and carbon isotope discrimination ($\Delta$) is higher in the drought-tolerant *Q. turbinella* compared to that in the moisture-requiring *Q. gambelii*. In C$_3$ plants, $\Delta$ depends upon $c_i/c_a$, the ratio of internal to ambient CO$_2$ concentration (Evans et al. 1986, Farquhar et al. 1989) and thus records the tradeoff between biochemical demand for CO$_2$ by photosynthetic enzymes in the chloroplasts and CO$_2$ supply through the stomata. Flanagan et al. (1992) found that leaf $\Delta$ and depth of water extraction from the soil (inferred from $\delta^D$ values of xylem water) were positively correlated among 4 woody species of the pinyon-juniper ecosystem in southern Utah. Since $\Delta$ is often correlated with stomatal conductance and water-use efficiency, it is an important parameter for unraveling the potential effects of hybridization on the water balance of woody perennials such as oak.

Hybrid oak populations in southern Utah also are useful for examining leaf structural and physiological controls on photosynthesis. The dependence of carbon isotope discrimination ($\Delta$) on leaf structural and chemical traits is typically studied at the interspecific and inter-population level (Vitousek et al. 1990, Meinzer et al. 1992, Sparks and Ehleringer 1997). Generally, $\Delta$ has been shown to decrease with leaf mass-to-area ratio and leaf nitrogen content. The *Q. gambelii* × *Q. turbinella* hybrid zones are intriguing because these species represent extreme leaf morphological types; small, thick leaves of *Q. turbinella* grade into large, thin-leaved *Q. gambelii* types in these extremely

![Fig. 1. Map of current northern boundaries of *Quercus gambelii* and *Q. turbinella* in the Intermountain region and location of relict hybrid clones in north central Utah. Map is based on information in Cottam et al. (1959) and Little (1971).]
variable hybrid populations. Integration between leaf structural and chemical traits and carbon isotope discrimination should be retained in these hybrid populations if $c/c_a$ is strongly controlled by these characters.

This study evaluated plant water relations, leaf $\Delta$, and leaf structural and chemical traits in *Quercus gambelii*, *Q. turbinella*, and their natural hybrids in southwestern Utah. We predicted that these 2 oaks would show differential capacities to take up summer rains in this natural setting and that hybrids would have intermediate water use and leaf gas exchange characteristics, similar to patterns observed in F1 hybrids in common gardens in Salt Lake City (Ehleringer and Phillips 1996). Of interest also was whether leaf structural and chemical traits that are often linked to $\Delta$ also would be correlated to $\Delta$ in hybrid populations, where there is a high potential for loss of trait integration because of recombination and back crossing.

**Materials and Methods**

The study was conducted in southeastern Utah in Washington County near the town of New Harmony within a large area of hybridization between *Quercus gambelii* and *Q. turbinella* (Fig. 1). Hybridization between these 2 oak species contributes to substantial leaf morphological variation in this area (Cottam et al. 1959, Tucker et al. 1961). Two hybrid populations were selected for study. Hybrid population 1 (HP1; 37°30′N, 113°19′W, 1707 m), located on a broad alluvial terrace above an ephemeral drainage (Pace Draw), is approximately 5 km north of the town of New Harmony. Hybrid population 2 (HP2; 37°30′N, 113°19′W, 1713 m) is 2 km northwest of HP1 near the same drainage. Vegetation at both sites is open scrub-oak woodland.

Twelve plants were selected from within each of these 2 hybrid populations for detailed morphological and physiological measurements. All plants used in the study were multi-stemmed adult plants and were 2–4 m in height. Plants were selected haphazardly with the intent of including the full range of leaf morphological variation that distinguishes the 2 oak species. Between 8 and 10 leaves were collected for morphological analysis on 24 August 1994 from each selected plant in the 2 hybrid populations and also from 5 plants from 1 nonhybrid population of each *Quercus* species. The “pure” stand of *Q. gambelii* (37°31′N, 113°20′W, 1798 m) was 3 km northwest of HP2 at the mouth of a mesic canyon feeding the drainage that passes near HP1 and HP2. The nonhybrid population of *Q. turbinella* was approximately 18 km south of New Harmony (37°20′N, 113°18′W, 1340 m).

Blade length, width, 1-sided area, and dry mass were determined for each leaf collected from the populations and averaged for each plant. Leaf mass-to-area ratio ($\text{LMA}$, g m$^{-2}$) was calculated from average mass and 1-sided area values from the leaves collected from each plant. These same leaves were analyzed for stable isotope ratios of carbon ($\delta^{13}$C) and total nitrogen concentration (N, g g$^{-1}$). $\delta^{13}$C was determined on finely ground, oven-dried (70°C for 48 h) blade tissue using an isotope ratio mass spectrometer (Delta S, Finnigan MAT, San Jose, CA) attached on-line to a CHN combustion furnace at the University of Utah Stable Isotope Facility for Environmental Research (SIRFER). $\delta^{13}$C was converted to carbon isotope discrimination values ($\Delta$) using an atmospheric $\delta^{13}$C value of −8‰ (Ehleringer and Osmond 1989, Farquhar et al. 1989). Nitrogen concentration was measured on these same samples using a Perkin-Elmer 2400 CHN analyzer (Norwalk, CN).

Preadawn leaf water potential (Ψpd) was determined for the same plants sampled above from all populations on 25 August 1994 using a Scholander-type pressure chamber (PMS Instruments, Corvallis, OR). Ψpd was measured between 0300 and 0530 h local time within 1 to 2 min after twigs were cut from the plants to minimize changes in Ψ due to water loss.

Plant water sources (winter recharge or summer monsoon-derived soil moisture) were inferred from $\delta$D values of plant xylem water. Although we did not measure isotopic values of soil, precipitation, or groundwater, it has been shown repeatedly for this region that winter moisture stored in deep soil layers is depleted in deuterium compared to water from surface soil layers that has been subjected to evaporative enrichment and mixed with isotopically heavy summer precipitation (Ehleringer et al. 1991, Flanagan et al. 1992, Phillips and Ehleringer 1994). Our interest here was simply to evaluate the covariation of $\delta$D with other physiological measurements rather than to identify the exact depth of water extraction by these trees or the proportion of water
obtained from different sources. We cut 3–4 suberized twigs at midday from different locations on a tree canopy the same day that Ψpd measurements were taken. Cut twigs were immediately enclosed and sealed in screw-cap glass vials using Parafilm and kept frozen in the lab until water was extracted using a cryogenic vacuum distillation technique (Ehleringer and Osmond 1989). Samples were then prepared for hydrogen isotope analysis by reacting 3 μL of the extracted water with 100 mg of zinc at 500°C for 1 h in sealed Pyrex tubes (method modified from Coleman et al. 1982). Zinc was obtained from J.M. Hayes, Departments of Chemistry and Geology, Indiana University. Hydrogen gas was analyzed for δD in the same manner as for δ13C at SIRFER. Standard lab waters were calibrated against samples of the international standards GISP and V-SMOW and were used in linear corrections of raw values obtained from the mass spectrometer.

Correlation, linear regression, and t tests were used to evaluate leaf morphological variation within and between oak populations and the associations between plant ecophysiological characteristics, leaf morphology, and chemistry. All analyses were performed using the JMP statistical software for Macintosh (Version 3.1, SAS Institute Inc. 1995).

**RESULTS**

Data for leaf structural and chemical traits were pooled between the 2 hybrid populations to examine broad trends for these characteristics. Blade length, width, LMA, and N concentration within the 2 hybrid populations were highly intercorrelated (Table 1). As expected, blade length, width, and area were all positively correlated. LMA was negatively correlated to length, width, and area, indicating that larger leaves were also thinner and likely contained less mesophyll tissue per unit leaf surface area. Conversely, leaf N concentration was positively correlated to leaf size. Because LMA declined with leaf size and N concentration increased in these hybrid populations, leaf N content (mmol N m–2) was constant over the range of leaf sizes (Table 1).

Leaf structural and chemical traits for plants in hybrid populations (HP1 and HP2) had values that spanned the range found in leaves from the 2 nonhybrid populations (Table 2). Leaves differed significantly between nonhybrid populations of *Q. gambelii* and *Q. turbinella* for all morphological traits and for leaf N concentration (Table 2). Larger leaves of *Q. gambelii* had lower LMA, higher N, but did not differ from leaves of *Q. turbinella* for leaf N content. Plants in the 2 hybrid populations, because of the high degree of trait variation, did not differ significantly from each other for any leaf morphological or chemical trait (Table 2).

 Dependence of carbon isotope discrimination (Δ) on leaf structural and chemical traits and plant water relations traits in the 2 hybrid populations were evaluated by regression (Figs. 2, 3). Variation in Δ was related significantly to leaf N concentration and LMA, but not to leaf nitrogen content (Fig. 2). Δ ranged almost 4‰ within these hybrid populations, with plants resembling *Q. turbinella* (high LMA and low leaf N concentration) having the lowest Δ values (near 16‰), and plants with leaves resembling those of *Q. gambelii* (low LMA and high N concentration) having the highest Δ values of up to 20‰.

Several rain events that preceded our sampling provided necessary conditions to evaluate water source variation within hybrid populations. Ψpd and δD were highly variable

within hybrid populations; \( \Psi_{pd} \) ranged from –1.5 to –0.2 MPa and \( \delta D \) ranged from –90‰ to –58‰. Groundwater and integrated summer precipitation collected from a site in Zion National Park, approximately 50 km to the east of our hybrid population site and at a similar elevation, were 95‰ and 30‰, respectively. Surprisingly, the regression of leaf \( \Delta \) on plant \( \delta D \) or \( \Psi_{pd} \) was not significant when hybrid populations were analyzed separately or together (Fig. 3). Although these water relations traits were not correlated with \( \Delta \), \( \Psi_{pd} \) was strongly correlated with \( \delta D \) (Fig. 4). \( \Psi_{pd} \) declined as \( \delta D \) increased across the 2 hybrid populations.

Although leaf N concentration differed significantly between the 2 nonhybrid populations (Table 2), \( \Delta \) did not (Table 3). Leaf carbon isotope discrimination, furthermore, was substantially higher in the pure \( Q. \) turbinella population than would be predicted from relationships found in hybrid populations (Fig. 2). \( \Delta \) was high in the nonhybrid population of \( Q. \) turbinella even though \( \Psi_{pd} \) was low. \( \delta D \) values for individuals within the nonhybrid \( Q. \) turbinella population were higher than for \( Q. \) gambelii, but these were not significantly different (Table 3).

**DISCUSSION**

Reduced monsoonal activity over the recent Holocene may have contributed to the extinction of \( Q. \) turbinella from northern Utah, but other climatic factors cannot be eliminated as possible causes. Although the present study was limited in scope, we found few differences among intermediate and parental phenotypes of \( Q. \) gambelii and \( Q. \) turbinella for summer precipitation use in hybrid populations in southwestern Utah. A few individuals that morphologically resembled \( Q. \) turbinella within the hybrid populations had \( \delta D \) values that were identical to that of winter precipitation, and these same individuals had high predawn water potentials. Presumably, these \( Q. \) turbinella phenotypes avoid drought through the summer because of their access to water stored in deep soil layers. However, more detailed isotopic and root profile studies would be needed to verify this hypothesis. If our water relations measurements represent general patterns for the entire growing season, then at least some \( Q. \) turbinella phenotypes have the potential to persist and maintain high physiological activity despite limited access to summer rainfall. Hybrid populations that occurred in northern Utah some time in the past presumably had comparable levels and patterns of variation for these water relations traits. Consequently, loss of monsoonal storms from the region would not have resulted in complete extirpation of \( Q. \) turbinella or morphologically similar individuals of hybrid origin. Although our conclusions are based on only a single sampling event during 1 yr, both

hybrid populations in our study yielded similar results.

Based on biogeographic analysis and seedling stress studies, Neilson and Wullstein (1983, 1985) concluded that the northern limit of Q. gambelii in Utah is constrained by the summer monsoon gradient and the probability of late spring frost determined by the polar front gradient. In addition to monsoon dynamics, the influence of freeze-thaw cycles may be exceptionally important in controlling the present northern limit of adult Q. turbinella. Hydraulic dysfunction caused by frost-induced xylem cavitation can be catastrophic for a diffuse-porous evergreen species (Sperry and Sullivan 1992, Sperry et al. 1994, Pockman and Sperry

Fig. 2. Dependence of leaf carbon isotope discrimination ($\Delta$) on leaf mass per unit area (LMA, g m$^{-2}$), nitrogen concentration (% g g$^{-1}$), and nitrogen content (mmol N m$^{-2}$) for plants selected within hybrid populations (HP1 and HP2) near the town of New Harmony in southwestern Utah. Regressions were fit to the pooled data for the 2 populations.
Apparent, the ring-porous *Quercus gambelii* will tolerate >90% loss of hydraulic conducting efficiency during winter and rely on new xylem production prior to leaf-out in spring to sustain high rates of transpiration (Sperry et al. 1994). Hybrid oak clones found in northern Utah are deciduous and potentially cope with freeze-thaw cycles in a manner similar to that in *Q. gambelii*. Neither the refilling of cavitated vessels with positive root pressure nor the ability to avoid freeze-thaw cavitation by having very small conducting elements seems like a plausible mechanism allowing the diffuse-porous and evergreen *Q. turbinella* to sustain significant hydraulic conducting efficiency in the cold climate presently characterizing northern Utah (Sperry et al. 1994). This diffuse-porous species likely experiences significant and nonreversible xylem dysfunction on an annual basis.

Carbon isotope discrimination in this study provides indirect evidence that hydraulic efficiency is reduced in *Q. turbinella* phenotypes in hybrid populations growing naturally near New Harmony in southwestern Utah and in an experimental garden at Salt Lake City studied by Ehleringer and Phillips (1996). Variation in $\Delta$ can be attributed directly to changes in stomatal conductance affecting $c_i/c_a$. Adjustments in stomatal conductance, furthermore, accompany changes in hydraulic conducting efficiency following hydraulic dysfunction in *Quercus* (Cochard et al. 1996). Low carbon isotope discrimination values measured in the common garden by Ehleringer and Phillips (1996) in northern Utah and at the northern limits of *Q. turbinella*’s range in the hybrid populations studied here may therefore reflect stomatal responses to reduced xylem conducting efficiency caused by frost. Notably, $\Delta$ in
the nonhybrid population of *Q. turbinella* at lower elevation and on a drier microsite south of New Harmony (18.0‰) was not different from that of *Q. gambelii* found in a common garden in northern Utah (18.8‰) or that of *Q. gambelii* in pure stands near New Harmony (18.0‰). *Δ* in *Q. turbinella* phenotypes was much reduced in the hybrid populations and in the common garden in Salt Lake City. It is likely that frost, in addition to reduced monsoon activity, played a role in the loss of adult *Q. turbinella* from northern Utah, but the combination of these climatic effects on this migration requires further study.

Leaf nitrogen concentration was almost twice as high for *Q. gambelii* as it was for *Q. turbinella* in pure and hybrid populations. Bulk leaf N concentration often reflects concentrations of photosynthetic enzymes, pigments, and electron transport components in leaves and is positively correlated with maximum photosynthetic rate within and among species of C3 plants (Evans 1989) and oaks (Reich et al. 1995). Plants morphologically similar to *Q. gambelii* in the hybrid populations maintained higher *Δ* (hence higher *c_j/c_a*) and leaf N concentration compared to *Q. turbinella* phenotypes. The positive relationship between *Δ* and N concentration in this study is opposite of what is expected if nitrogen forms a suitable proxy for photosynthetic capacity. Higher N (greater photosynthetic capacity) should cause *c_j/c_a* and *Δ* to decline, not rise. Furthermore, we found no correlation between *Δ* and nitrogen content per unit leaf area, and a negative relationship between *Δ* and LMA. Vitousek et al. (1990) observed similar correlations between leaf δ13C and LMA for *Metrosideros polymorpha* across an elevational gradient in Hawaii, and attributed δ13C variation to variation in leaf internal resistance. High internal resistance reduces CO2 concentration at sites of carboxylation in the chloroplast and potentially lessens discrimination against 13CO2 (Evans et al. 1986). Although we found patterns of leaf carbon isotope variation and LMA in oak hybrid populations that were similar to that reported by Vitousek et al. (1990) for *Metrosideros*, we have no direct estimates of *c_j/c_a* from instantaneous gas exchange measurements to demonstrate conclusively the magnitude of internal resistance. In any event, some combination of high internal resistance and low *c_j/c_a* produced the relatively high discrimination values in *Q. turbinella* phenotypes in our study.

Carbon isotope discrimination in the oak hybrid populations was not related to water source (δD) or plant water potential (*Ψ_{pd}*), but *Ψ_{pd}* did during our August sampling period. Tucker et al. (1961) noted that these oak populations apparently have undergone repeated hybridization and backcrossing. Hybridization and further recombination in these populations may have reduced the level of integration between traits that control rooting depth and leaf *Δ*. Leaf gas exchange traits and rooting patterns appear to be functionally integrated among parental and F1 hybrids in the artificially maintained common garden populations near Salt Lake City (Ehleringer and Phillips 1996), but these traits are not functionally integrated in natural hybrid populations in southwestern Utah. We found no correlation between either predawn water potential or δD and *Δ* within our hybrid populations (Fig. 3). Introggression of genes into populations of *Q. turbinella* that control development of a deep root system remains a possibility and would explain the high levels of variation in δD among *Q. turbinella* phenotypes in hybrid populations.
