Quinoa (*Chenopodium quinoa* Willd.) is a food crop cultivated by subsistence farmers and commercial growers on the high Andean plateau, primarily in Bolivia, Peru, and Chile. Present interest in quinoa is due to its tolerance of harsh environments and its nutritional value. It is thought that the seed storage proteins of quinoa, particularly the 11S globulins and 2S albumins, are responsible for the relatively high protein content and ideal amino acid balance of the quinoa seed. Here we report the genomic and cDNA sequences for two 11S genes representing two orthologous loci from the quinoa genome. Important features of the genes and the proteins they encode are described on the basis of a comparison with homologous 11S sequences from other plant species. Gene expression and protein accumulation determined via reverse transcriptase real-time PCR and SDS-PAGE analyses are described. Additionally, we report the phylogenetic relationships between quinoa and 49 other species by using the coding DNA sequence for the well-conserved 11S basic subunit.

Keywords: quinoa, RT-PCR, 11S globulin, seed storage protein, gene expression.

Introduction

Quinoa (*Chenopodium quinoa* Willd.) is a dicotyledonous pseudocereal native to the Andean Altiplano (high plains). It is an important cultural and dietary component of the Quechua and Aymara people, who have lived on the Altiplano for centuries (Risi and Galwey 1984). Quinoa thrives in a wide variety of environments extending from mountain valleys and coastal foothills to the semiarid and cool Andean Altiplano. Ca. 12%–14% of the dry mass of quinoa seed is protein (Cardoza and Tapia 1979; Chauhan et al. 1992), and its amino acid composition exceeds the Food and Agriculture Organization's recommendations for human protein consumption (Ruas et al. 1999). The percent protein in quinoa seed is high compared with that in the seeds of cereal crops such as rice, corn, and millet (Charalampopoulos et al. 2002). Seed storage proteins are thought to play a vital role in determining the nutritional value of quinoa seed (Brinegar 1997).

Storage proteins accumulate in developing seeds as a source of nitrogen, carbon, sulfur, and amino acids for use in germination and growth of the developing seedling. These protein reserves are stored in the cells of the endosperm and embryo in protein storage vacuoles or specialized aggregates called protein bodies, which are assembled within the endoplasmic reticulum (Herman and Larkins 1999). Seed storage proteins are generally classified according to their solubility: albumins, globulins, prolamins, and glutelins, which are soluble in water, saline solutions, alcohol, and alkali solutions, respectively (Osborne 1924). They are further classified on the basis of their sedimentation coefficients ($S_{20,w}$). Globulins generally fall into two major groups based on these coefficients: the 7–8S vicilin type and the 11–12S legumin type. Because legumin-type seed storage proteins vary in size, the 11–12S globulins are referred to collectively in other species as legumins.

The nucleotide sequence of genes encoding legumins has been reported for economically important seed crops such as rice (Okita et al. 1989; Wen et al. 1989; Takaiwa et al. 1991), oat (Shotwell et al. 1988; Schubert et al. 1990; Tanchak et al. 1995), maize (Woo et al. 2001; Yamagata et al. 2003), and soybean (Momma et al. 1985; Utsumi et al. 1987; Nielsen et al. 1989; Xue et al. 1992), and the crystal structure of an 11S globulin from soybean has been determined (Adachi et al. 2003). The 11S globulin is a hexamer consisting of six pairs of acidic and basic subunits, with each subunit pair connected by a disulfide bond. It is translated as a single precursor containing acidic and basic subunits as well as a signal peptide responsible for translocation of the precursor into the endoplasmic reticulum (ER). The 11S proprotein assembles as a trimer in the ER and is transported to the vacuole via the Golgi apparatus. In the vacuole, the proprotein is cleaved by asparaginyl endopeptidase to yield the acidic and basic subunits connected by a disulfide linkage. The hexamer assembles directly after this cleavage event (Dickinson et al. 1989).

The origin and early evolution of legumin structure has been discussed by Shutov and Bäumlein (1999), who describe legumin evolution from a germinlike ancestor. After divergence of seed storage proteins into vicilin and legumin classes, each independently acquired their storage-related properties. Seed storage proteins and analogous proteins seem to have an ancient history, as they are present in the early progenitors of plants, including mosses and fungi (Shutov et al. 2003). Thus, these gene sequences may prove useful as phylogenetic markers in molecular evolution studies and may provide insight into

Manuscript received July 2007; revised manuscript received September 2007.

evolutionary modifications under the selective constraints of either better storage capabilities or degradation. The study of conserved and variable regions and how they relate to structure and metabolism may provide valuable information about how these protein sequences may be altered and improved for nutritional purposes in quinoa and other species.

The 11S globulin and the 2S albumin are the two major storage proteins in quinoa seed (Brinegar 1997). The 11S globulin in quinoa has a typical 11S quaternary structure, with an estimated native molecular mass of 320 kDa. The acidic and basic polypeptides have average relative molecular masses of 35.5 and 22.5 kDa, respectively (Brinegar and Goundan 1993). Here we report the genomic and cDNA sequences of two orthologous 11S genes from quinoa. We present data on 11S gene expression during seed development and the corresponding accumulation of 11S globulin within the seed. Coding DNA sequences were used to conduct a phylogenetic study between the 11S sequence in quinoa and the homologous seed storage proteins of diverse species. We discuss legumin molecular evolution in light of the results of our analysis.

Material and Methods

Plant Materials

Quinoa Real was grown under greenhouse conditions at Brigham Young University. Tissue for use in DNA extractions was collected from the first two true leaves of 2- to 4-wk-old plants. Harvested tissue was immediately frozen and stored at −80°C. Quinoa accessions NL-6, KU-2, Maniqueña, Mocko, Ollague, Ratuqui, Sayaña, Chucapaca, and 0654 were planted simultaneously and grown under greenhouse conditions. Temperatures were 20°–25°C during the day and 15°–18°C at night, and plants were exposed to 12 h of daylight. Seed was collected at 8-d intervals after anthesis until maturity from each accession and was immediately frozen and stored at −80°C.

cDNA and Genomic Sequencing

Genomic DNA was extracted from quinoa Real according to the protocol reported by Saghai-Maroof et al. (1984). An initial fragment of the quinoa 11S gene was obtained by amplification of genomic DNA using degenerate PCR primers designed from a partial quinoa 11S amino acid sequence (Brinegar and Goundan 1993) as well as an alignment of a cDNA sequence from *Amaranthus hypochondriacus* (Barba de la Rosa et al. 1996). The forward primer sequence was 5′-AATGGKGTGGARGARACYATTTGC-3′, and the reverse was 5′-TGTKKGCGTTKAGGTTSYAGTG-3′. The gene fragment was used as a probe to screen the quinoa developing seed cDNA library reported by Coles et al. (2005). Positive clones were selected and their identities confirmed by Southern blotting. Two clones homologous to 11S genes from other species were isolated from the cDNA library and have been assigned GenBank accession numbers AY562549 and AY562550. A quinoa bacterial artificial chromosome (BAC) library was screened as previously described, and a second nonoverlapping clone was identified in addition to the clone already reported by Stevens et al. (2006). The 11S genomic and cDNA inserts within positively identified clones were sequenced by primer walking at the Brigham Young University DNA Sequencing Center (Provo, UT).

RNA Extraction and Relative Quantification

Seeds were ground to a fine powder in liquid nitrogen, and total RNA was extracted using an RNeasy Plant Mini Kit (Qiagen, Valencia, CA). The RNA was quantified using a NanoDrop ND-1000 spectrophotometer (NanoDrop Technologies, Wilmington, DE). Primers and probes were designed for the 11S gene and the *GAPDH* gene: 11S forward 5′-GGCGGTCGCTTCCAAGA-3′, reverse 5′-TTGCGAAAATGTGGCCTTGAC-3′, probe 5′-CCAACACCAGAAGATCA-3′; *GAPDH* forward 5′-GGTTACAGTCATTCAGACACCATCA-3′, reverse 5′-AACAAAGGGAGCCAAGCAGTT-3′, probe 5′-CGCTTCCTGTACCAC-3′. Using the *GAPDH* gene as an endogenous control, we quantified multiplexed RNA samples by using a TaqMan One-Step RT-PCR Master Mix Reagents Kit on a 7300 Real-Time PCR System (Applied Biosystems, Foster City, CA). Each sample contained 0.5 μg of total RNA. The samples were held at 48°C for 30 min, heated to 95°C and held for 10 min, followed by 40 repetitions of temperatures at 95°C for 15 s and 60°C for 60 s.

Globulin Extraction, Quantification, and Separation by SDS-PAGE

Fifty milligrams of seed collected at 8-d intervals after anthesis was ground to a fine powder, and 500 μL of water was added to each sample. The samples were shaken at 4°C for more than 1 h and centrifuged at 13,000 *g*, and the supernatant containing the albumin fraction was removed. The pellet was washed twice, using the same procedure described above, and dried. To each pellet, 400 μL 0.5 M NaCl/50 mM Tris-HCl, pH 8.0, was added. The suspension was shaken at 4°C for more than 1 h and was centrifuged at 13,000 *g*, and the supernatant containing the globulin fraction was collected into separate tubes. Total protein in the globulin fraction was quantified using a BCA Protein Assay Kit (Pierce, Rockford, IL) on a NanoDrop ND-1000 spectrophotometer. The samples were diluted 1 : 2 with Laemmli Sample Buffer and separated with SDS-PAGE on Ready Gels (BioRad, Hercules, CA). Gels were fixed overnight according to the manufacturer's instructions and visualized using Flamingo Fluorescent Gel Stain (BioRad) under UV light.

Taxonomic Sampling and Sequence Alignment

Legumin sequences from 50 different species of plants were assembled using MEGA3 software (Kumar et al. 2004). These species and the GenBank accession numbers for their legumin sequences are listed in table 2. Coding DNA sequences were downloaded from GenBank. Using the amino acid sequence of the 11S seed storage protein from *Chenopodium quinoa* (GenBank accession no. AAS67037) as a query sequence, we preformed a BLASTp search (Altschul et al. 1990). Only legumin sequences from different plant species with E values less than 1e-10 were chosen, as to include sequences substantially similar and likely related by descent to the 11S gene in quinoa. One coding DNA legumin sequence from each species, except for quinoa and species from the Fabaceae family, was selected

on the basis of similarity to the quinoa 11S sequence. Two major legumin genes are present in many species in the Fabaceae family (Yagasaki et al. 1997), and sequence information for both genes from these species, if available, was included in the analyses. The two quinoa sequences included in the analysis corresponded to the coding DNA sequences of cDNA clones 17B7 and 8B14 (GenBank accession nos. AY562549 and AY562550, respectively). The legumin basic subunit, a well-conserved sequence region, was chosen to improve the alignment because distantly related sequences were being compared. The selected coding DNA legumin sequences were translated into amino acid sequences by using MEGA3. Amino acid sequences were aligned with CLUSTAL W using the BLOSUM matrix and used as a template for the nucleotide alignment. CLUSTAL W performs multiple sequence alignments of nucleotide or protein sequences by using a progressive alignment algorithm including a gap cost model, which penalizes insertions and deletions according to a linear function and sequence similarity, for construction of a guide tree (Thompson et al. 1994).

Phylogenetic Reconstruction

Trees were constructed using distance, maximum parsimony, and Bayesian methods. Branch support of parsimony and Bayesian reconstructions was tested using bootstrapping and posterior probabilities, respectively. MODELTEST (Posada and Crandall 1998) was used to select the most appropriate likelihood-based nucleotide substitution model.

Distance, maximum parsimony, and Bayesian analyses are three kinds of tree reconstruction methods that rely on different assumptions. Neighbor-joining is a distance method that expresses distance as a fraction of sites that differ between sequences. Maximum parsimony assumes that the tree generated by the fewest number of sequence changes between taxa is the most likely one. Bayesian analysis relies on the concept of posterior probabilities, based on a postulated model of evolution that represents the probability of the relationship given the data. Trees are generated on the basis of the model and the sequence alignment. Periodic sampling, in this case every 1000 tree generations, allowed us to compute a consensus tree by using the software package PAUP* (Swofford 2001).

MODELTEST (Posada and Crandall 1998) is a program designed to assign the most statistically appropriate model of evolution to the alignment under evaluation. It employs two statistical approaches to model selection, the likelihood ratio test (LRT) and the Akaike Information Criterion (AIC). The LRT is generated by pairwise comparisons between the likelihood score of nested alternative hypotheses under a complex model. The AIC compares several models concurrently to determine the model that best fits the data while penalizing increasing numbers of parameters in the model (increasing parameters will always generate a better fit for the data but does not always represent the best model). The general time-reversible (GTR) model assumes that the probability of changing from one base into another is the same in one direction as it is in the reverse direction. Therefore, among four nucleotides, there are six possible substitution rates. Additional parameters allow probabilities to be assigned to each site for designation to a specific rate category.

Measures of branch support for parsimony and Bayesian reconstructions can be tested by using bootstrapping and posterior probabilities, respectively. Bootstrap values are expressed as probabilities that taxa within a clade are always grouped within that clade. Posterior probabilities express the probability of relationships given the data and the model of evolution.

The phylogenetic signal of the data was explored using distance tree reconstruction in MEGA3. Parsimony reconstruction was accomplished using PAUP*, version 4.0b10 (Swofford 2001), and a bootstrap analysis with 1000 replicates was conducted, with bootstrap values over 70 representing supported relationships. Bayesian consensus tree reconstruction was accomplished using MrBayes, version 3.0b4 (Ronquist and Huelsenbeck 2003), with default values as the starting parameters. Five million tree generations were conducted, and trees were saved every one-thousandth generation. The consensus tree was generated with a burn-in at 20,000 tree generations, and posterior probabilities above 90 represented supported relationships. Members of the Coniferales, Ginkgoales, and Gnetales were assigned as a monophyletic outgroup based on putative sequence similarity to ancient taxa (Shutov et al. 1998).

Results

Isolation and Characterization of the Quinoa 11S Genes

Two BAC clones, representing distinct 11S seed storage globulins from quinoa, have been identified and characterized. The nucleotide sequences of the coding and flanking regions of both genes were obtained directly from the BAC clones by using a primer walking strategy, and these have been assigned GenBank accession numbers DQ917482 and DQ917483. Coding and flanking regions of BAC clone DQ917482 are 99.5% identical to those of cDNA clone AY562549; likewise, the coding and flanking regions of BAC clone DQ917483 are 99.8% identical to those of cDNA clone AY562550, suggesting that the cDNAs represent transcripts of the two 11S gene loci. We have named the two loci 11SA and 11SB, respectively. A comparison between 11SA and 11SB shows 97% homology in the coding regions and 92% homology in the untranslated regions. Each gene includes three introns whose positions are conserved between the two genes. The 11SA gene encodes a polypeptide of 480 amino acids, whereas the 11SB gene encodes a polypeptide of 479 amino acids.

An alignment of the amino acid sequences of the two quinoa 11S proteins clearly shows that the quinoa 11S proteins are similar to the 11S seed storage proteins found in other species (fig. 1). The first 25 hydrophobic amino acid residues are typical of a signal peptide found in other legumin-like seed storage proteins. The conserved asparaginyl endopeptidase recognition site (between asparagine 292 and glycine 293 in 11SA and between asparagine 291 and glycine 292 in 11SB) at which the precursor polypeptide is separated into acidic and basic subunits is highlighted in figure 1. Cleavage at this conserved site yields acidic subunits with 266 or 267 amino acids and basic subunits with 188 amino acids. As shown in figure 1, there are four conserved cysteine residues involved in disulfide bond formation in 11S proteins of other species.

Fig. 1 Alignment between the 11SA (AAS67036) and 11SB (AAS67037) amino acid sequences from quinoa and between the AlaBlb (BAC78522) and A3B4 (BAB15802) amino acid sequences from soybean. Shaded portions represent identical amino acids between the four sequences. The asterisk represents cleavage sites. Underlined cysteine residues represent those involved with disulfide bond formation (Adachi et al. 2003).

11S Gene Expression and Protein Accumulation

To determine the 11S gene expression profile, we collected quinoa seeds at 8- and 10-d intervals after anthesis until desiccation from nine accessions: NL-6, KU-2, Mocko, Maniqueña, Ollague, Ratuqui, Sayaña, Chucapaca, and 0654. Accessions were chosen on the basis of geographic origin (ecotype) and maturation rate (table 1). Altiplano ecotypes originate either in the Salares (areas containing salt flats) or in valley regions, while coastal ecotypes are native to the Chilean lowlands. Total RNA was extracted and quantified from each accession, and relative quantification of 11S mRNA in seeds from different developmental stages was determined by one-step reverse transcriptase real-time PCR using the *GAPDH* gene as an endogenous control. Relative amounts of 11S globulin protein were assayed via SDS-PAGE. Figure 2 shows the results of the 11S mRNA and globulin quantification at specific days after anthesis (DAA). The bars in the graph (fig. 2) depict the relative quantity of globulin mRNA at each developmental time point, whereas the bands below the bars are a qualitative representation of globulin protein as seen on SDS-polyacrylamide gels. In general, only minor amounts of 11S mRNA transcripts were detected during early seed development, followed by a substantial accumulation of 11S protein concurrent with peak gene expression levels. As seeds became mature, expression decreased and protein accumulation remained high.

On the basis of days to desiccation and 11S RNA and protein accumulation patterns, five classes of maturation rates were identified and are listed together with accession names and geographic locations in table 1. Type I consists of two Chilean lowland accessions (KU-2 and NL-6) that showed peak gene expression and 11S globulin accumulation at 24 DAA and maturity between 32 and 40 DAA. Type II consists of Maniqueña and Mocko, two Salares Altiplano ecotypes that showed peak gene expression at 24 DAA, detectable 11S globulin quantity occurring at 32 DAA, and maturity achieved between 40 and 50 DAA. Ollague (Salares Altiplano), Ratuqui, and Sayaña (Northern Altiplano) were included as type III accessions and showed peak 11S transcript levels and substantial

Table 1

Quinoa Accession, Location, and Maturation Type for Which 11S Gene and Protein Expression Data Were Obtained

Accession	Ecotype[a]	Maturation type
KU-2	Coastal	I
NL-6	Coastal	I
Maniqueña	Salares	II
Mocko	Salares	II
Ollague	Salares	III
Ratuqui	Altiplano	III
Sayaña	Altiplano	III
Chucapaca	Altiplano	IV
0654	Valley	V

[a] Valley and Salares are subdivisions of the Altiplano type.

11S globulin accumulation at 40 DAA and reached maturity between 50 and 60 DAA. Chucapaca (Salares Altiplano ecotype) and 0654 (Peruvian valley ecotype) were included as types IV and V, respectively. Both showed detectable 11S protein quantities at 50 DAA; however, Chucapaca reached maturity at ca. 60 DAA, and 11S transcript levels reached a maximum of 40 DAA, while 0654 reached maturity significantly later (between 60 and 70 DAA) and showed maximal 11S transcript levels at 50 DAA. As shown in figure 2, the increases in 11S globulin levels in these different varieties appear to be correlated with the expression profiles for the 11S gene.

Phylogenetic Analysis of 11S Seed Storage Proteins

A comparison of 11S globulins from quinoa and 49 other species was performed to determine the phylogenetic relationship of the quinoa protein with homologous proteins from other plant species. The coding DNA sequences of complete legumin sequences from 50 different plant species were translated, aligned, and evaluated for phylogenetic signal quality. Common name, species, families, and orders for the plant species used in the phylogenetic analysis are presented in table 2. Alignments were created from the whole or portions of the legumin sequence. Using distance-based and maximum parsimony methods for tree reconstruction in MEGA3, we evaluated preliminary trees to assess the quality of the alignments. An amino acid alignment generated from the basic subunit sequence of the legumin gene resulted in detectable amino acid conservation, consistency between trees generated by the aforementioned methods, and taxonomic clustering. It was therefore selected for further analysis.

A second phylogenetic analysis of the basic subunits was performed using the Bayesian algorithm in MrBayes. In order to do this appropriately, we used MODELTEST to determine the likelihood model with the fewest number of parameters that failed to differ from the most general model. This analysis resulted in the identification of the GTR model with measures of invariable sites (*I*) and rate heterogeneity (*G*) as the most appropriate model for these data. Bayesian approaches for phylogeny reconstruction do not initially assume specific parameter values but iterate through the process of calculating trees and then parameter values from those trees until parameters converge on values that are emergent from the data. For this analysis, we let the algorithm iterate through 5 million tree generations.

Figures 3 and 4 show the parsimony and Bayesian tree reconstructions, respectively. In both reconstructions, with posterior probabilities and bootstrap values of 100, the two

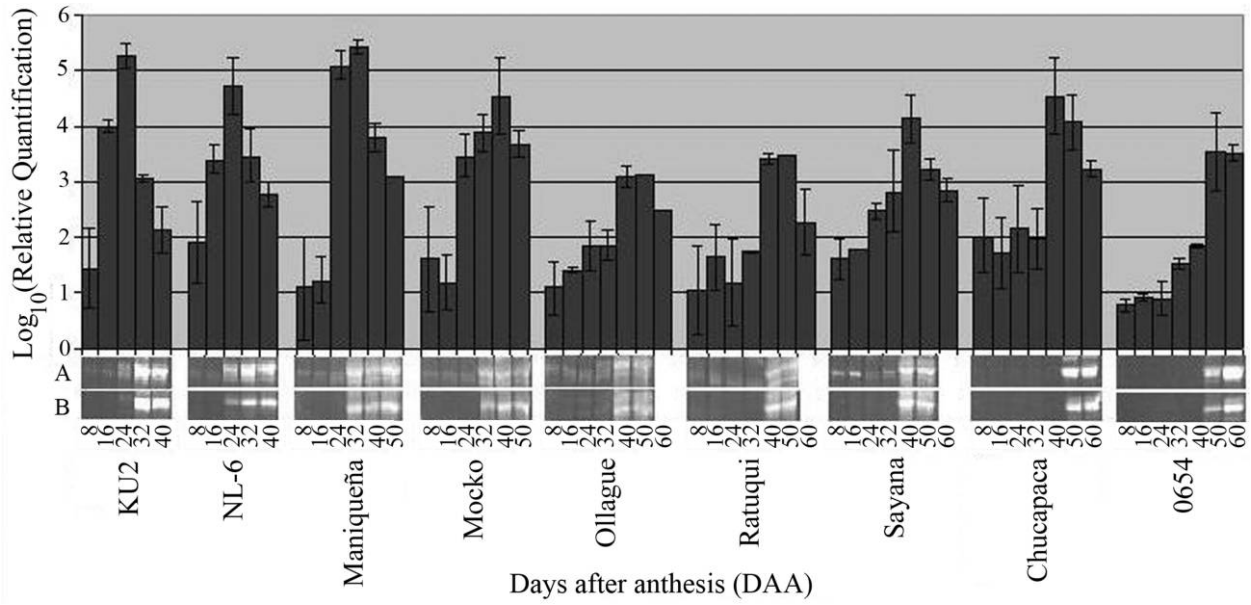

Fig. 2 11S gene expression and protein accumulation during the development of quinoa seeds. Quinoa accessions and days after anthesis are listed on the horizontal axis. Gene expression was measured in $\log_{10}$(relative quantification) units using the *GAPDH* gene as an endogenous control. The results of the SDS-PAGE analysis are shown below the graph. *A*, Acidic subunit of the 11S polypeptide; *B*, basic subunit of the 11S polypeptide.

[a] Type of subunit.

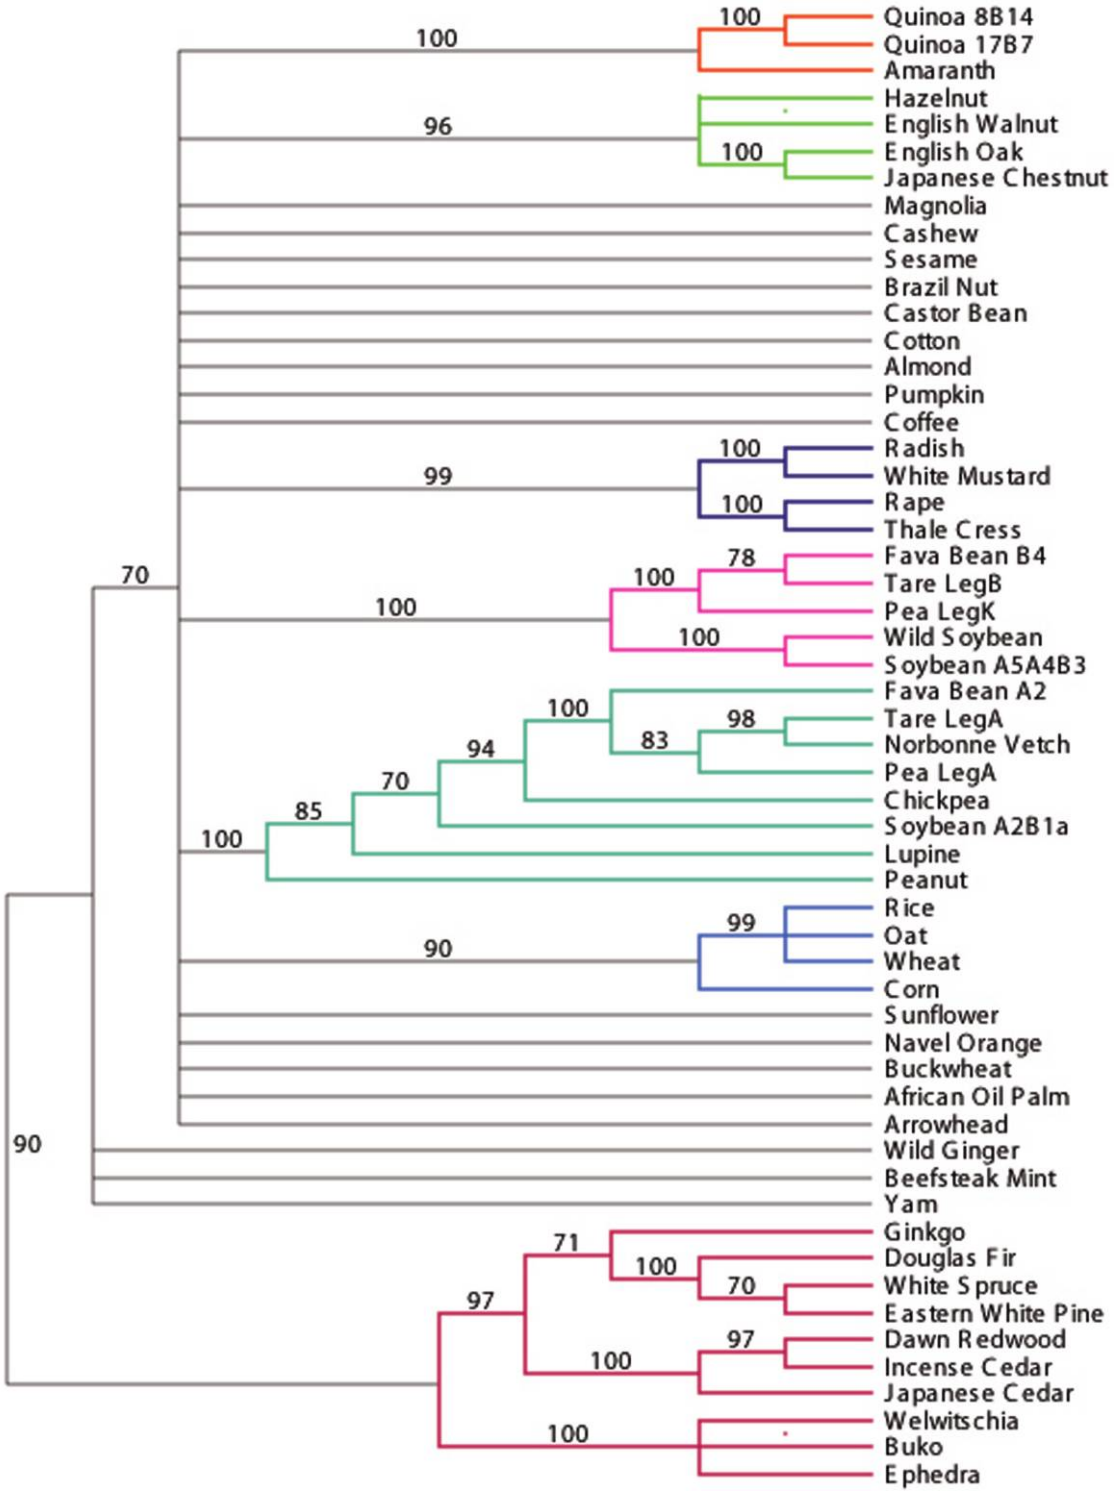

Fig. 3 Parsimony tree reconstruction of legumin basic subunit coding DNA sequences. Unresolved portions of the tree represent bootstrap values under 70. Colored portions represent monophyletic groups identified by both Bayesian and parsimony tree reconstructions.

quinoa 11S sequences form a monophyletic group with an *Amaranthus hypochondriacus* 11S sequence (GenBank accession X82121), the only other reported sequence from a species within the Amaranthaceae family. On the basis of amino acid alignments, the 11S basic subunit shows more than 74% sequence identity between amaranth and quinoa. Other monophyletic and well-resolved taxonomic groups represented in both trees include taxa from the Poaceae, Brassicaceae,

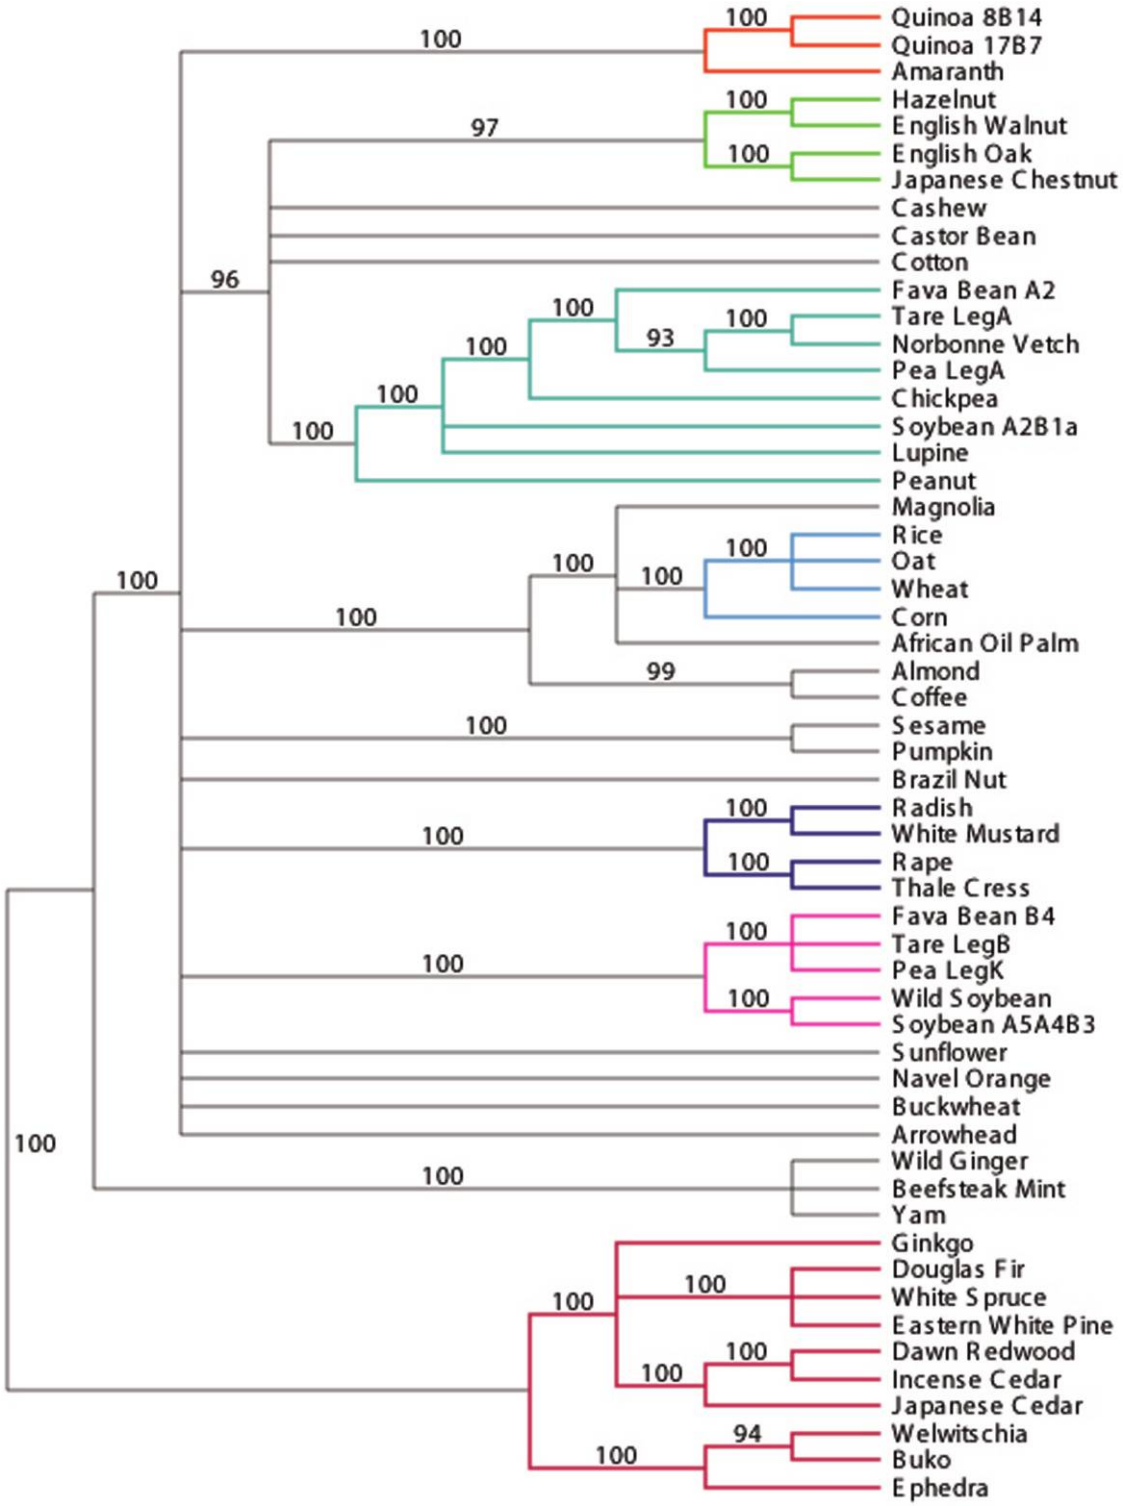

Fig. 4 Bayesian consensus tree reconstruction of coding DNA sequences of the legumin basic subunit. Unresolved portions of the tree represent posterior probabilities below 90. Colored portions represent monophyletic groups identified by both Bayesian and parsimony tree reconstructions.

Cupressaceae, and Pinaceae families, the Fagales order, and the clade for gymnosperms. The sequences from members of the Fabaceae family form two monophyletic groups, each containing 11S sequences derived from different subfamilies. The phylogenetic relationships between the gymnosperm outgroup taxa are well resolved in both trees and reveal a clear bifurcation of angiosperm and gymnosperm legumin gene lineages.

Discussion

11S Gene Sequences

BAC clones and cDNAs representing two quinoa genetic loci, 11SA and 11SB, that encode an 11S legumin-like seed storage protein have been identified and characterized. The cDNAs for 11SA and 11SB have 99.7% and 99.9% sequence identity with their corresponding BAC clone sequences. The small sequence divergence observed between the cDNAs and the BACs is most likely due to sequence heterogeneity in quinoa Real, which was used to construct both the BAC and the cDNA libraries.

On the basis of the deduced amino acid sequence analysis, the domains and residues required for processing and assembly are conserved in the quinoa 11S preproprotein. The first 25 amino acid residues constitute a putative signal peptide responsible for localizing the proprotein to the lumen of the ER. As reported by Brinegar and Goundan (1993), the first 21 amino acids of the N-terminus of the quinoa 11S basic subunit are GLEETICSARLSENIDDPSKA, suggesting that the asparaginyl endopeptidase cleavage site is between Asp292 and Gly293 in 11SA and between Asp291 and Gly292 in 11SB. The position of the cleavage site and the N-terminal sequence of the basic subunit are highly conserved among 11S proteins (Utsumi 1992). Glycinin, the legumin-like protein from soybean, has four major protein binding domains, as revealed by its crystal structure (Adachi et al. 2003). These domains are also found in the quinoa 11S protein, suggesting that it has a hexamer quaternary structure similar to that of glycinin. Four cysteine residues that participate in disulfide bond formation in other species are found in the quinoa sequences (fig. 1). The first two cysteine residues (Cys37 and Cys70) form an intrachain disulfide bridge within the acidic subunit, and the second two cysteine residues (Cys113 and Cys299/300) form an interchain disulfide bridge between the acidic and basic subunits (Utsumi 1992).

The quinoa 11S amino acid sequence is well balanced and shows a high level of essential amino acids with respect to human nutrition. Typical of 11S storage proteins, the quinoa protein is rich in glutamate/glutamine, aspartate/asparagine, arginine, serine, leucine, and glycine (Brinegar and Goundan 1993). We note, however, that the 11S gene is only one of two major seed storage proteins in quinoa seed and that it is the combined contribution of the 11S and 2S seed proteins that produce quinoa's unique seed protein quantity and composition. Thus, the cloning, sequencing, and expression characterization of the 2S albumin remains an important goal to complete our understanding of how quinoa seeds accumulate such a high quantity of protein and essential amino acids.

Expression Patterns of 11S Genes in Different Quinoa Accessions

The gene expression and protein data presented here indicate that the accumulation of seed storage protein is correlated to maturation rate. For example, 11S mRNA begins peaking at 16 DAA and 11S protein at 24 DAA in the early-maturing varieties KU-2 and NL-6, whereas similar increases in mRNA and protein accumulation are not seen in late-maturing varieties until at least 24 and 32 DAA, respectively. In extreme cases (i.e., Chucapaca and 0654), the 11S protein is not detected until 50 DAA. These data suggest that high expression of 11S mRNA occurs, on average, during late maturation, consistent with the pattern of storage protein (including 11S) accumulation during seed development in other plant species (Nakamura et al. 2004). While analyzing plants grown in the greenhouse is important and informative, we recognize that future field-based experiments are needed to confirm our observations. Furthermore, a quantitative study of total protein content per seed is needed to determine whether the timing of gene expression has an effect on the overall quantity of seed protein in quinoa.

Phylogenetic Relationships between Legumins of Various Species

The legumin coding DNA sequence of the basic subunit was used to analyze phylogenetic relationships between the 11S gene of quinoa and other species. The basic subunit of legumin is well conserved and contains sequence elements that are necessary for its proper assembly and packaging. These include the amino acids involved in the recognition of the peptide cleavage site between the acidic and basic subunits and a cysteine residue involved in disulfide bond formation (Adachi et al. 2003). Indeed, several researchers have used the legumin basic subunit sequence or portions of the basic subunit for studies involving the molecular evolution of seed storage proteins (Fischer et al. 1996; Häger and Wind 1997; Shutov and Bäumlein 1999).

The maximum parsimony and Bayesian analyses used in the phylogenetic reconstructions reported here (figs. 3 and 4, respectively) use very different assumptions. Maximum parsimony assumes that the best tree is one in which evolutionary steps are minimized, while Bayesian analysis implements a model of evolution in addition to the sequence data in order to maximize the probability of a tree. Because one method lacks outside parameters, assuming that one evolutionary event is just as likely as another, and the other uses established parameters in order to predict associations, we assumed that relationships established by both reconstructions would be well supported. Indeed, all monophyletic groups defined by the maximum parsimony tree were also supported by the Bayesian tree. Both phylogenetic trees were well resolved between closely related taxa, and the placement of the quinoa 11S sequences with amaranth exhibited posterior probabilities and bootstrap values of 100.

In both analyses, all monophyletic groups were equally supported; however, the data suggest that the Bayesian analysis was better suited for resolving relationships between more distantly related taxa than was the parsimony method. Indeed, most unresolved portions of the Bayesian reconstruction angiosperm backbone had posterior probabilities just under 90. Third and fourth nodes with posterior probabilities of 83 and 88, respectively, were present following the bifurcation of lower angiosperm legumin sequences in ginger, mint, and yam. The third node represented the divergence in a sequence from arrowhead, while the fourth node separated two clades from the remaining angiosperms, one including sequences from members of the Poaceae family (magnolia, African oil palm, almond, and coffee) and one composed of sequences from sesame, pumpkin, orange, and buckwheat. Although these relationships are

based on posterior probabilities under 90, they are still well supported by the majority of the data.

Following the divergence between gymnosperms and angiosperms, there appears to have been a sudden increase in sequence divergence among the legumin genes as evidenced by the presence of multigene families and the lack of resolution in the phylogenetic tree reconstruction. Multigene families for the legumin-like genes have been identified in many species, including those of legumes (Domoney et al. 1986; Nielsen et al. 1989; Heim et al. 1994), brassicas (Pang et al. 1988; Breen and Crouch 1992; Depigny-This et al. 1992), and cereals (Shotwell et al. 1988; Okita et al. 1989). Multigene families have also been identified in gymnosperms (Häger et al. 1995; Wind and Häger 1996; Häger and Wind 1997). Interestingly, these gymnosperm genes have a much higher degree of sequence homology with each other than do the legumin gene sequences of the angiosperms. We also note that there does not appear to be an 11S multigene family in quinoa (Stevens et al. 2006), nor have there been any identified in amaranth (Barba de la Rosa et al. 1996). However, other 11S genes or pseudogenes may be present in the quinoa genome but have not yet been identified because of sequence dissimilarity.

The ability to resolve relationships between sequences from gymnosperms and other ancient taxa is shown by both parsimony and Bayesian trees. We note, however, that the radiation at the angiosperm level, as well as the lack of sufficient sequence data to match the broad range of angiosperm species, creates some challenges when using the legumin sequence as a phylogenetic tool. Indeed, without adequate sequence data and the added complication of multigene families that may have arisen at different evolutionary points, it is difficult to know whether homologous genes are being compared, and thus, taxa may be grouped inappropriately. However, it appears that there is sufficient phylogenetic signal, even from diverse species, to support future studies investigating the molecular evolution of legumin genes in angiosperms.

Quinoa is a putative allotetraploid, and we postulate that the two copies of the 11S gene may be located on homeologous chromosomes and may represent genes present in the diploid ancestors of quinoa. Although the sequences for both loci are similar, transcript levels from each may not be equal. Alternatively, it is also possible that the unusually high protein content of quinoa is a direct result of tetraploidization and the unaltered expression of both genes because polyploidy generally increases gene expression levels overall (Osborn et al. 2003). Indeed, seeds containing higher protein reserves for germination and the developing seedling may have been a selective force in the tetraploidization of quinoa.
