(Received 7 September 1994; accepted for publication 3 October 1994)

A high-pressure optical cell has been designed that achieves an effective separation between the chemical sample and the pressurizing medium and system. This design limits possible sample contamination and catalytic effects under supercritical fluid sample conditions. Laser flash photolysis experiments were carried out on molybdenum hexacarbonyl dissolved in supercritical CO₂. The thermal ring closure reaction of the species Mo(CO)₅L₂, where L is 2,2'-bipyridine was found to proceed at rates comparable to those measured previously in liquid benzene or toluene. Much larger activation volumes were found for the reaction in supercritical CO₂ than in liquid toluene. © 1995 American Institute of Physics.

I. INTRODUCTION

Liquified gases and supercritical fluids (hereafter SF) are presently recognized as unique reaction media for new chemistry in a wide range of thermal and photoinduced processes. Such media exhibit a remarkable temperature and pressure sensitivity that can cause dramatic changes in properties such as relative permittivity, diffusion characteristics, and solubility. It is especially the solute-solvent interactions that differ significantly from those prevailing in liquids at normal densities, such that these reaction media can be used simultaneously as solvent and reaction partner. For these reasons, the application of SF in extraction and other separation processes has been an active area of research and development in chemical process industries in recent years.

Poliakoff and co-workers were among the first groups to apply SF to the study of organometallic chemical reactions, because of the fundamental importance of these reactions in fields as diverse as industrial catalysis and biological processes. They have, in particular, studied photochemical reactions of organometallic species in supercritical Xe, CO₂, and C₂H₄. We have in recent years developed an interest in the substitution behavior of metal carbonyl complexes, especially of reactive intermediates produced during flash photolysis of M(CO)₆ (M=Cr, Mo, W). Since it is generally known that metal carbonyls are very sensitive to the presence of impurities and possible catalytic effects of metallic surfaces, it was essential to design an experimental procedure in which the investigated chemical system is in no direct contact with the pressurizing medium and system. Earlier work in the liquid phase included the use of a pillbox optical cell in order to separate the chemical system from the high-pressure medium and system. The optical cell design reported in the present paper permits an efficient separation of the SF sample system from the pressurizing medium and system.

II. EXPERIMENTAL SECTION

A. Flash photolysis apparatus

A schematic design of the pulsed laser flash photolysis apparatus is shown in Fig. 1. A Quanta Ray DCR-2 Nd:YAG laser sent a 6 ns laser pulse beam (about 100 mJ/pulse) at \( \lambda = 355 \text{ nm} \) through the sapphire window of a high-pressure cell at 90° from the path of the transient absorption probe beam. The detection system consisted of an Oriel 75 W Xe lamp, a Durum monochromator, and a Hamamatsu 1P28 photomultiplier tube (PMT). The voltage signal from the PMT was sent to a LeCroy 9400 oscilloscope interfaced (GPIB) to a 386-based computer (ARCHÉ DX-40). Data were analyzed by KINFIT software from OLIS (Bogart, GA).

B. Pumping system

The pumping system used in this study was based on a syringe-type system in which the fluid reservoir was the pump cylinder. A syringe-type pump was used because of the pulseless flow characteristics of this type of pump. The pumping system was modified from an ISCO 314 liquid delivery syringe pump. Basically, a pressure transducer and associated control electronics were added according to the work of Van Lenten and Rothman in order to provide for pressure control of the fluid instead of volumetric flow control. The full details, including electrical and mechanical drawings, of the modifications to the ISCO 314 pump can be found elsewhere. In addition, the pressure was monitored by a pressure transducer (SETRA 280E) with a pressure meter (DATUM 2000™) which had been calibrated to an accuracy of ±10 psi (6.8×10⁻² MPa).

C. High-pressure cell

The homemade high-pressure cell was machined from stainless steel, and contains four windows each of which is at 90° to its neighbors (Fig. 2). Temperature was monitored by a temperature probe (Omega CF-000-RTD-4-60-2) which enters through one of the cell windows. The temperature probe
FIG. 1. Apparatus for laser flash photolysis studies in supercritical fluid samples.

was calibrated against a mercury thermometer from the National Bureau of Standards, and its accuracy is about ±0.1 °C. The three optical windows were lined up to transmit the probe beam and the laser beam. On the top of the high-pressure cell, there was a three-way stainless-steel valve connected to the high-pressure pump and also to a pressure relief outlet (Fig. 3).

The diagram of the optical window is shown in Figs. 2 and 3. A Teflon delta ring and a silicone O-ring were used to seal the gap between the window and the high-pressure cell. A stainless-steel cap was used to hold a sapphire plate against the surface of the window plug. The sealing between the 10-mm-thick sapphire plate and the window plug depends on the smoothness of the plug surface in contact with the sapphire plate. The surface was carefully polished on a glass plate by hand to get a flat surface, using 1200, 3000, 8000, 14000, 50000, and 100000 mesh diamond grit, successively.

A major improvement in our experiments was the use of an isolated reaction cell inside the high-pressure cell to avoid any possible contamination and catalytic effects from the O-rings and other cell components. The reaction cell consists of a homemade, square, quartz cuvette, and a specially designed Teflon cap (Fig. 4). The cuvette is 13.5 mm×13.5 mm×25 mm, and is fixed on a Teflon base inside the high-pressure cell. The surface of the cuvette is 90° to the laser beam to allow the laser beam to strike on an even surface, thus avoiding the observation of diffusion phenomena. A small, round quartz tube was used in earlier experiments, but because of the uneven scattering of the laser beam and the high diffusion coefficient of the SF, reproducible kinetic traces were very hard to obtain. A 40–50 cm long Teflon

capillary tube (i.d. = 0.4 mm) threaded through a hole in the center of the cap was used to control the diffusion of the reactants and to keep them inside the cuvette. One end of the capillary was melted with a heat gun, reshaped into a thin plate, and placed against the bottom of the cap. A small Teflon screw was used to fix this end inside the cap. The space around the cap was used to hold the capillary by winding the tube around the cap. This arrangement protected the reaction solution from contamination, and allowed us to stabilize reaction conditions and to obtain highly reproducible kinetic traces.

The high-pressure cell could also be mounted in the cell compartment of a Hewlett-Packard diode array spectrophotometer that enabled the recording of UV-VIS spectra during flash photolysis experiments.

D. Procedures

The 2,2'-bipyridine, pyridine, and molybdenum hexacarbonyl (98%) used in this study were obtained from Aldrich. SFC grade carbon dioxide was purchased from Scott Specialty Gases. A mixture of the chemicals, along with a Teflon coated magnetic stirring bar, were placed in the quartz cuvette. After placing the cuvette inside the cell, the cell was filled with SFC grade carbon dioxide (at least three times) to eliminate any air from the high-pressure cell. Hot water was then circulated through the high-pressure cell wall to raise the temperature to 323 K. Next, the high-pressure syringe pump was used to pressurize the cell to 10.3 MPa. The critical pressure and temperature of carbon dioxide are 7.5 MPa and 304 K, respectively. Before each laser pulse, a waiting period of 2 min was required to stabilize the reaction conditions after stopping the stirrer in order to obtain reproducible kinetic traces.

After a series of rate measurements, ice water was circulated through the cell wall to cool the cell down to 273 K, during which supercritical CO₂ was converted to the liquid phase. Then the pressure was released very slowly using the three-way valve. Because CO₂ was vented as the headspace gas through the Teflon capillary, the reactants and products of the experiment remained in the cuvette instead of escaping to contaminate the whole high-pressure vessel.

III. RESULTS AND DISCUSSION

The advantage of the newly designed optical cuvette is the restriction of the chemical system to be investigated to a small reaction chamber (~1.3 mL) within the pressure vessel. The long Teflon capillary allows flow of gaseous and liquid CO₂ to the sample, but limits diffusion of the sample out of the cuvette to the pressure vessel. With the aid of the magnetic stirrer, it was possible to rapidly homogenize the reaction mixture in the SF phase between flash photolysis experiments.

In general, flash photolysis of M(CO)₆ results in the loss of CO and the rapid formation of M(CO)₅(solvent). In the presence of a strong nucleophile L, the coordinated solvent molecule will be displaced to produce M(CO)₅L as shown in Eq. (1). When L is a bidentate ligand, M(CO)₅L will undergo a subsequent thermal reaction to produce the ring-closed M(CO)₅L species as shown in Eq. (2).

\[
\text{M(CO)}_6 \xrightarrow{\text{hv}} \text{M(CO)}_5 + \text{CO}, \\
\text{fast}
\]

\[
\text{M(CO)}_5 \xrightarrow{\text{slow}} \text{M(CO)}_5\text{(solvent)}, \\
\text{L} \xrightarrow{k_1} \text{M(CO)}_5\text{L} \xrightarrow{k_2} \text{M(CO)}_5\text{L} + \text{CO}. \\
\]

Our earlier work has shown that both reactions (1) and (2) strongly depend on the nature of the metal center M and the nucleophile L. Changes in M and L can result in a gradual change in the intimate nature of the substitution mechanism. The nature of the solvent controls the lability of the M(CO)₅(solvent) species. With detailed mechanism information available on these systems, we have now used these reactions to probe the usefulness of supercritical CO₂ as a reaction medium for such reactions.

Flash photolysis of a mixture of Mo(CO)₆ and pyridine (py) in supercritical CO₂ resulted in a rapid increase in absorbance at 390 nm, followed by almost no further change in absorbance at longer reaction times (see Fig. 5). When the CO₂ pressure was increased from 10.2 to 23.8 MPa no significant changes in the kinetic trace were observed. The coordination of py to the molybdenum carbonyl intermediate produced during flash photolysis is expected to be fast on the time scale of these experiments, based on kinetic data reported for this reaction in benzene, viz. 5.4x10⁴ M⁻¹s⁻¹ at 24 °C. Thus flash photolysis of mixtures of Mo(CO)₆ and py in supercritical CO₂ rapidly produces Mo(CO)₅py. The formation of this product was confirmed by the UV-VIS spectrum recorded after completion of the experiment and release of the CO₂ pressure.

Similar reactions were studied using 2,2'-bipyridine (bipy) instead of py. The UV VIS spectrum recorded immediately following the flash clearly indicates the formation of the ring-opened Mo(CO)₅bipy species (λₘₐₓ = 390 nm in benzene). During the following few seconds, the spectrum changes to that for the ring-closed Mo(CO)₅bipy species. In this case, measurements at 490 nm, the absorbance maximum reported for Mo(CO)₅bipy in benzene as solvent showed well behaved first order traces (Fig. 6). Similar measurements at 390 nm, corresponding to the absorbance maximum of Mo(CO)₅bipy, showed an almost instantaneous absorbance increase followed by a subsequent slow increase due to the formation of ring-closed Mo(CO)₅bipy. Through
out the series of measurements, the concentration of bipy had no effect on the observed first-order rate constant, in agreement with expectations for ring-closure reactions. Furthermore, the $k_{obs}$ value of 2.7±0.2 s$^{-1}$ at 323 K and 10.2 MPa is of the same order of magnitude as rate constants reported for this reaction in benzene and toluene. The reaction undergoes a remarkable acceleration on increasing the CO$_2$ pressure as shown in Figs. 6 and 7. The results in Fig. 7 clearly indicate that the rate acceleration is largest close to the critical point, and decreases with increasing pressure. In terms of volumes of activation, the data correspond to a value of $-600$ cm$^3$ mol$^{-1}$ in the low-pressure range and $-79$ cm$^3$ mol$^{-1}$ in the high-pressure range. Such a significant pressure dependence of the volume of activation must be related to the compressibility of the medium, which corresponds to a low density, weak solvent at low pressure and a high density, stronger solvent at high pressure. Similar results have been reported for the decomposition of $\alpha$-chlorobenzylmethyl ether in supercritical 1,1-difluoroethane and for the tautomeric equilibria of 2-hydroxypridine, and 2-pyridone in supercritical 1,1-difluoroethane. The ring-closure reaction of Mo(CO)$_3$bipy is therefore accompanied by a large volume collapse at pressures close to the critical point where the medium is highly compressible. The effect is significantly smaller in the compressed SF medium where the observed activation volume resembles that observed in the liquid phase, viz. $-3.9\pm0.6$ cm$^3$ mol$^{-1}$ in toluene. From these data it can be concluded that the ring-closure reaction is characterized by a highly ordered transition state.

The results of this investigation have clearly demonstrated how the new optical cell design can be used to perform routine kinetic investigations in supercritical fluids. The experimental data permit a direct comparison of the mechanistic behavior of metal carbonyl species in supercritical CO$_2$ with mechanistic behavior in conventional organic solvents.

An important observation is the extreme pressure sensitivity of the ring-closure reaction of Mo(CO)$_3$bipy which clearly demonstrates unique properties of this unconventional reaction medium.
