We propose an ultracompact high-efficiency polarizing beam splitter that operates over a wide wavelength range and is based on a hybrid photonic crystal and a conventional waveguide structure. Within a small area ($15\ \mu\text{m} \times 10\ \mu\text{m}$), this polarizing beam splitter separates TM- and TE-polarized modes into orthogonal output waveguides. Results of simulations with the two-dimensional finite-difference time-domain method show that 99.3% of TM-polarized light is deflected by the photonic crystal structure (with a 28.0-dB extinction ratio), whereas 99.0% of TE-polarized light propagates through the structure (with a 32.2-dB extinction ratio). Wave vector diagrams are employed to explain the operation of a polarizing beam splitter. Tolerance analysis reveals a large tolerance to fabrication errors. © 2003 Optical Society of America

The use of hybrid photonic crystal (PhC) and conventional waveguide (CWG) structures was recently proposed as a way to achieve ultracompact planar lightwave circuits.¹ Hybrid structures are formed by integration of a two-dimensional PhC region with CWGs to manipulate the direction of light propagation in a very small area (lateral dimension of the order of the waveguide mode size). In this Letter we present the numerical design and analysis of an ultracompact high-efficiency polarizing beam splitter with a high extinction ratio. Numerous approaches to achieving waveguide polarizing beam splitters have been reported in the literature^{2–6}; they typically require relatively long waveguide structures (length of the order of millimeters). The approach presented in this Letter occupies an area of only $15\ \mu\text{m} \times 10\ \mu\text{m}$. Moreover, we show that its performance accommodates reasonable fabrication tolerances.

The geometry of a high-efficiency PhC–CWG polarizing beam splitter is shown in Fig. 1(a). Light incident from the left is split into vertical and horizontal output waveguides according to its polarization (vertical, TM; horizontal, TE; TM and TE are the electric fields out of plane and in plane, respectively). The waveguides are designed to be single mode for wavelengths near $1.55\ \mu\text{m}$ ($2\text{-}\mu\text{m}$ width, $n_{\text{core}} = 1.500$, $n_{\text{clad}} = 1.465$). The PhC is composed of a square array of silicon posts ($n = 3.481$). The boundaries between the PhC region and the CWGs are created by cuts in the Γ –M direction of the PhC, which form an angle of 45° with the input waveguide. The lattice constant and the radius of the Si posts of the PhC are 380 and 86.8 nm, respectively.

The spectral response of this structure for both TM- and TE-polarized incident light is shown in Fig. 1(b) as calculated by the finite-difference time-domain (FDTD) method⁷ with Berenger's perfectly matched layer boundary conditions.⁸ In the simulations a single-mode source is used to launch TM or TE light into the input waveguide and a Poynting vector calculation is used to monitor the optical power in the output

waveguides, which is divided by the incident power to yield the efficiency with which light is directed into the output waveguides. From Fig. 1(b) it is clear that this hybrid structure splits TM and TE polarization to the output waveguides effectively for a wide wavelength range. The waveguide inside the PhC region is designed to follow the direction of propagation of the TE-polarized light, which leads to a $0.75\text{-}\mu\text{m}$ shift of the horizontal output waveguide in the $-y$ direction from the input waveguide, as shown in Fig. 1(a).

The magnitude squared of the time-averaged electric field (TM) and magnetic field (TE) at $\lambda = 1.55\ \mu\text{m}$ are shown in Figs. 2(a) and 2(b), respectively. TM-polarized light is reflected with 99.3% efficiency at the PhC surface and guided along the vertical output waveguide; 0.06% of the incident light passes through the PhC region. In TE-polarized light, 99.0% passes through the PhC region into the horizontal waveguide and 0.16% is reflected into the vertical output waveguide. The TM and TE output extinction ratios are 28.0 and 32.2 dB, respectively.

Wave-vector (i.e., equifrequency) diagrams are useful as an aid in understanding how the hybrid structure operates. In Fig. 3, wave-vector diagrams for TM and TE polarization are shown for $\lambda = 1.55\ \mu\text{m}$. The horizontal axes of the wave-vector diagrams correspond to the Γ –M direction of the PhC, which forms the incident interface of the PhC. The square and diamond insets in Figs. 1 and 3, which indicate the first Brillouin zone of the PhC, show how the physical geometry is related to the wave vector diagram. In Fig. 3, the solid semicircles in the upper half-space are allowed wave vectors in the non-PhC region (assuming that this region is quasi-homogeneous with a refractive index of 1.485) and the dotted curves are the wave vectors of allowed propagation modes in the PhC. The solid arrows denote propagation directions of the incident, reflected, and refracted light. The propagation direction of the refracted light in the PhC is determined by the group-velocity direction, which is calculated by the gradient of the dispersion

surface.^{9,10} The grating vector associated with the periodicity at the boundary of the PhC is represented by the dashed arrows in Fig. 3.

From Fig. 3(a) we can easily see that there is no possible mode in the PhC region for TM-polarized light incident along the input waveguide at a 45° angle to the PhC surface. Moreover, there are no allowed diffraction orders from diffraction by the periodic PhC boundary. Therefore, only zero-order reflection is allowed for light incident upon the PhC boundary, and this reflected light couples into the vertical output waveguide. TE-polarized light at 45° incidence to the PhC boundary, however, has a possible propagation mode in the PhC region, although there are still no allowed diffraction orders, as shown in Fig. 3(b). Because the allowed wave vectors in the PhC for TE polarization

form a semicircle, the PhC region can be considered an effective homogeneous material. The effective index calculated from the wave-vector diagram in Fig. 3(b) is 1.682. This value is smaller than the effective index calculated from the area-weighted average index of the PhC because the field propagating through the PhC region is localized primarily in the low-index material.

Using the effective index and considering the PhC region as an isotropic material, we can explain why 99.0% of TE-polarized light can be coupled into the horizontal output waveguide. The Brewster angle calculated for the PhC's effective index is 48.56°, which is close to the incident angle (45°). The reflections at both interfaces are therefore very small [0.015% for Fresnel reflection calculated with effective indices of the non-PhC region (1.485) and the PhC region (1.682)]. Because the reflections at both interfaces are so small, high coupling efficiency into the horizontal output waveguide for TE-polarized light is obtained.

Fig. 2. Magnitudes squared of time-averaged (a) electric field (TM) and (b) magnetic field (TE) at $\lambda = 1.55 \mu\text{m}$ calculated by the two-dimensional FDTD method. The Yee cell size in the FDTD simulation is 10 nm.

In addition, we examined the performance of the polarizing beam splitter as a function of potential fabrication errors that affect Si-post radii and periods and positional and angular misalignment of the PhC region with respect to the waveguides over the wavelength range $1.53\text{--}1.62 \mu\text{m}$ (C and L bands for optical communication). Results for a variation in Si-post radii from 80.8 to 90.8 nm (20-nm range for the diameter) show that the TM efficiency varies from 93.0% to 99.3% , whereas the corresponding range for the TE efficiency is $94.5\text{--}99.0\%$. At a wavelength of $1.55 \mu\text{m}$ the efficiency for the TM-polarized light at the vertical output waveguide is in the range $98.7\text{--}99.3\%$, whereas more than 97.2% of TE-polarized light is coupled into the horizontal output waveguide. The efficiencies of TM- and TE-polarized modes are greater than 94% for changes of the PhC period from 370 to 400 nm over the C and L bands. Also, the TM and TE efficiencies are greater than 95% for $\pm 0.5\text{-}\mu\text{m}$ misalignment of the PhC region in both the x and the y directions. A PhC angular misalignment greater than $\pm 1^\circ$ is required before the TM efficiency decreases 95% over the wavelength

range. Actual fabrication angular misalignments are of course much smaller than a degree. Our tolerance simulations show that the proposed polarizing beam splitter design has reasonable fabrication tolerances for operation over the C and L bands.

In conclusion, we have proposed an ultracompact ($15 \mu\text{m} \times 10 \mu\text{m}$ area) polarizing beam splitter design with high efficiency (99.3% for TM-polarized light and 99.0% for TE-polarized light) and a high extinction ratio (28.0 dB for TM polarization and 32.2 dB for TE polarization) composed of a PhC embedded in low-index contrast CWGs. The proposed polarizing beam splitter has reasonable tolerances to fabrication errors.
