CARBON ISOTOPE DISCRIMINATION IN THE C₄ SHRUB ATRIPLEX CONFERTIFOLIA ALONG A SALINITY GRADIENT

Darren R. Sandquist and James R. Ehleringer

ABSTRACT—Carbon isotope discrimination (Δ) was measured for leaves of Atriplex confertifolia along a salinity gradient in northern Utah. Over this gradient, the variation of Δ values was high for a C₄ species, and the Δ values were positively correlated with salinity in both years of the study. Of the possible explanations for this pattern, the Δ results are consistent with the notion that salinity induces an increase in the bundle sheath leakiness of these C₄ plants.

Key words: carbon isotope ratio, salt stress, bundle sheath leakiness, halophyte, desert ecology.

The analysis of carbon isotope ratios ([¹³C]/[¹²C]) has become a useful tool for understanding various integrated aspects of plant metabolism, including numerous investigations of plant-environment interactions. The impact of environmental factors on carbon isotope discrimination (Δ) by plants with C₃ photosynthesis has been well studied; however, only a limited number of studies have examined variation of Δ values in C₄ plants (O'Leary 1988, Farquhar et al. 1989, Peisker and Henderson 1992). In part, this disparity stems from C₄ plants having much smaller variation of Δ values than C₃ plants. Additionally, Δ values in C₃ plants have been correlated with water-use efficiency, and this has lead to an emphasis on applying carbon isotope analyses to breeding programs (Farquhar et al. 1989, Ehleringer et al. 1993). However, a few recent studies have demonstrated that variation of Δ values in C₄ plants may reflect environmental influences on physiological function (Bowman et al. 1989, Meinzer et al. 1994). In this study we examined variation of Δ values in a C₄ perennial shrub, Atriplex confertifolia (Torr. & Frem.) Wats., and its relationship to natural conditions of soil salinity.

The Δ value of a C₄ plant integrates two factors that can impact productivity: (1) the ratio of intercellular to ambient CO₂ concentration (c/i), which can reduce photosynthetic activity when low, and (2) bundle sheath leakiness (φ), which reduces photosynthetic efficiency when high. Farquhar (1983) modeled the relationship between these factors and carbon isotope discrimination in C₄ plants as

\[ \Delta = a + (b_3 + b_4 \phi - a) \frac{c_i}{c_a}, \]

where a (4.4%) is discrimination against the heavier [¹³CO₂] molecule relative to the lighter [¹²CO₂] based on differential rates of diffusion, b₃ (29%) is the discrimination due to a greater affinity for [¹²CO₂] relative to [¹³CO₂] by ribulose bisphosphate carboxylase (Rubisco), and b₄ (typically ~ -5.2%) is discrimination based on the steps leading to, and including, CO₂ fixation by phosphoenol pyruvate carboxylase (PEPC) after atmospheric CO₂ enters the leaf. The b₄ term varies slightly as a function of temperature and is negative (greater proportion of [¹³CO₂]) due to fractionation associated with the hydration of CO₂ to HCO₃⁻ (Mook et al. 1974). The discrimination terms of Equation 1 (a, b₃, and b₄) are constants, for the most part, and thus differences among Δ values are the result of changes in φ and/or c_i/c_a during CO₂ assimilation.

In C₄ plants, CO₂ is initially fixed by PEPC in the mesophyll cells, transported and decarbboxylated in the bundle sheath cells, and then refixed by Rubisco. However, before the assimilation by Rubisco a fraction of the CO₂ may diffuse out through apoplastic portions of the bundle sheath cells. This is known as "leakiness" and is thought to be reduced by suberization of bundle sheath surfaces (Farquhar 1983). This leakiness, however, may be increased by environmental stresses, such as salinity (Bowman et al. 1989), and an increase
in leakiness represents an energetic cost to the plant as a result of incomplete carbon assimilation or overcycling (Ehleringer and Pearcy 1983, Jenkins et al. 1989, Henderson et al. 1992).

Leakiness affects $\Delta$ because it causes the bundle sheath cell to become an open system and therefore allows expression of discrimination by Rubisco ($b_3$). The proportion of $CO_2$ that leaks out of the bundle sheath cell ($\phi$) modifies the degree to which $b_3$ is expressed and thereby determines the relationship between $\Delta$ and $c_i/c_a$ (Eq. 1). At low $\phi$ values the relationship between $\Delta$ and $c_i/c_a$ is negative, at high $\phi$ the relationship is positive, and at $\phi = 0.32$, $\Delta$ is constant at 4.4‰ regardless of $c_i/c_a$. Equation 1 also predicts that for any given $c_i/c_a$, an increase in $\phi$ results in an increase in $\Delta$. Given these relationships, variation of $\Delta$ values in $C_4$ plants can provide an indication of bundle sheath leakiness and its relationship to environmental stresses.

To date, much work investigating variation of $\Delta$ in $C_4$ plants has come from either laboratory gas exchange studies (Evans et al. 1986, Bowman et al. 1989, Henderson et al. 1992) or theoretical models (Peisker 1982, Farquhar 1983, Peisker and Henderson 1992). There is little direct information on environmental stresses that influence $\Delta$ in natural populations of $C_4$ plants (except see Walker and Sinclair 1992). Here we report on changes in $\Delta$ values for the $C_4$ species *Atriplex confertifolia* found along a natural salinity gradient in Utah. The purpose of this study was to determine if $\Delta$ values changed in relation to soil salinity under field conditions, and if these changes corresponded to variation in $\phi$ values. Two previous laboratory studies have shown that higher soil salinity does increase $\Delta$ values in $C_4$ plants and that this change is a result of greater $\phi$ (Bowman et al. 1989, Meinzer et al. 1994). For *A. confertifolia*, we hypothesized that the same trend would be found over a transect of naturally increasing soil salinity.

**METHODS**

**Study Sites**

Four study sites of increasing salinity were chosen along a south-to-north transect in the northern end of Skull Valley (Tooele County, UT) flanking the western slope of the Stansbury Mountain Range. The four sites range in elevation from 1366 m to 1286 m (Fig. 1). Site 1 (1366 m) is dominated by sagebrush (*Artemisia tridentata*) with low densities of *Atriplex confertifolia*, *Juniperus osteosperma*, and *Tetradymia spinosa*. Weedy grasses and annual species of the Chenopodiaceae are also found within disturbed areas of this and all other sites. Greasewood (*Sarcobatus vermiculatus*) is the dominant species at sites 2 (1317 m) and 3 (1294 m) with *A. confertifolia* co-occurring in low frequency. Site 4 (1286 m), along the margins of the salt flats, is a heterogeneous site with a mixed community of salt-tolerant species. *S. vermiculatus* is the dominant species with moderate densities of *Allanrolfla occidentalis*, *Atriplex gardneri*, *A. confertifolia*, *Chrysothamnus viscidiflorus*, *Kochia americana*, and *Suaeda torreyana*.

Weather data for this transect are taken from the Grantsville weather station (Grantsville, Tooele County, UT, 1307 m) located 17.3 km E and 8.2 km S from the center of our study transect.

**Leaf and Soil Samples**

Leaves of *Atriplex confertifolia* and soil samples were collected from each of the four transect sites in October 1991 and 1992, with the help of the 1991 and 1992 Plant Ecology classes from the University of Utah. Recently matured leaves of *A. confertifolia* were collected from five to eight individuals per site in 1991 and three per site in 1992. Leaf samples were oven-dried (70°C, 7 d), ground with mortar and pestle, and analyzed for carbon isotopic composition (Windy Ike, Delta S mass ratio spectrometer, Finnigan-MAT, San Jose, CA) relative to the Pee Dee Belemnite standard. Analyses were done at the Stable Isotope Ratio Facility for Environmental Research (SIRFER, University of Utah, Salt Lake City, UT). Carbon isotope ratio values ($\delta$) were transformed to discrimination ($\Delta$) values as

$$\Delta = (\delta_a - \delta_p)/(1 + \delta_p),$$

where $\delta_p$ is the measured carbon isotope ratio of the plant, and $\delta_a$ is the carbon isotope ratio of $CO_2$ in the atmosphere ($-0.08$ or $-8$‰; Farquhar et al. 1989). The standard per mil (‰) notation is used throughout for ease of presentation, and the overall, long-term error
Soil samples were collected from two depths (15–20 cm and 40–60 cm) in two to six excavation pits at each site. Approximately 200 g of freshly extracted soil from each hole and depth was placed immediately into soil canisters, sealed, and kept cool until analysis in the laboratory. In the lab one subsample per canister was removed for salinity analyses. The remaining soil was used for gravimetric water content determination based on the difference between soil fresh (wet) weight and dry weight (i.e., water content) relative to the soil dry weight. Soils were dried at 70°C for 7 days.

In 1991 the soil salinity analysis was based on electrical conductivity (EC) of an aqueous solution extracted from a 1:2 soil:deionized water mixture, and in 1992 from a 1:5 soil:deionized water mixture. There was no evidence that the 1:2 mixture was ion saturated; thus, to standardize these ratios, the ECs of samples using a 1:2 solution were extrapolated to EC based on a 1:5 ratio assuming a linear dilution relationship. Tests confirmed that this extrapolation was valid even for EC values higher than those found in actual field samples.

Although a more standard procedure for salinity determination is the “soil paste” method, the 1:5 ratio method we used is recommended as a simpler technique to determine relative salinity contents (Rhoades 1982) and is suitable for the purposes of this study (i.e., standardized comparison of relative salinities among sites). Additionally, the ECs of 1:5 ratio extracts are highly correlated with soil paste ECs for soils within and near our transect (D. G. Williams unpublished data). Electrical conductivity is reported in μhmhos cm⁻¹ (1 μhmhos cm⁻¹ = 0.1 mS m⁻¹ = 0.502 mM NaCl), and the data were log transformed for statistical analyses. Interannual comparisons of means for each soil trait were done by t tests, and correlations between soil trait and plant carbon isotope discrimination means were determined by Pearson product-moment correlation.

RESULTS

Transect Characterization

Salinity increased across the gradient in both the 1991 and 1992 samples; electrical conductivity increased by two orders of magnitude over the entire transect (Table 1). Site 1 was the least saline, and salinity progressively increased toward the highly saline site 4.

There were few differences between years in soil electrical conductivity. Significant differences were found at only two sites and at only one depth per site. Furthermore, sites gave opposite results: soils of site 3 at the 15–20-cm depth had greater conductivity in 1991 than 1992 (t = 4.33, P < .01), and soils from site 1 at the 40–60-cm depth had higher conductivity in 1992 than in 1991 (t = 4.60, P < .01).

Gravimetric water content also increased over the transect from site 1 to site 4 (Table 1). Soil water content was somewhat greater in...
TABLE 1. Soil properties at two depths for sites 1-4 along the study transect (n = number of pits, one sample for each depth per pit). Soil water content was measured as gravimetric water content, and electrical conductivity is of an aqueous extract from 1:5 soil-water mixture (extrapolated for 1991 from 1:2 ratio; see text).

1991 than in 1992, but significant differences at both depths were found only at site 1 (15-20-cm depth, t = 3.34, P < .05; 40-60-cm depth, t = 3.52, P < .05). Rainfall over the 10wk period prior to sampling in 1991 was much greater than that of 1992 (82.5 mm vs. 18.8 mm), which likely accounts for the trend of greater water content in the soils during the 1991 sample period.

Carbon Isotope Discrimination

Along the transect the carbon isotope discrimination for Atriplex confertifolia ranged from a low of 4.74 ± 0.96‰ at site 1 in 1992, to a high of 6.55 ± 0.11‰ at site 3 in 1991 (Fig. 2). This range of nearly 2‰ is high for C4 plants (Farquhar et al. 1989). The mean Δ value was always greater than 4.4‰, and for only a single sample was the individual shrub value less than 4.4‰. These high Δ values indicate that the mean φ values were always greater than 0.32 (Eq. 1).

With respect to the environmental parameters examined along the transect, mean leaf Δ was not significantly correlated with water content during any observation, but was positively correlated with log EC (Fig. 2). Inclusion of the notably low Δ value of site 4 in 1991 resulted in a nonsignificant, positive trend (but when excluded, Δ was significantly correlated with log EC in 1991 at the deeper soil depth, R = 1.0, P < .01). In 1992 there was a highly significant, positive correlation of Δ and log EC for both the shallow soils (R = .978, P < .05) and deeper soil depths (R = .999, P < .001) (Fig. 2).

DISCUSSION

Variation in carbon isotope discrimination values of C4 plants is, in part, dependent upon the proportion of CO₂ that is initially fixed by PEPC and ultimately diffuses out of the bundle sheath cells without being refixed (i.e., the leakiness, φ). Leakiness might be influenced by environmental stresses, such as salinity (Bowman et al. 1989, Meinzer et al. 1994), because such stresses could disrupt membrane properties or the biochemical coordination between the C4 and C3 cycles operating in the mesophyll and bundle sheath cells, respectively (Peisker and Henderson 1992). The other component influencing variation of Δ in C4 plants is c/f/cₐ. Figure 3 illustrates how the relationship between Δ and c/f/cₐ depends upon the value of φ (from Eq. 1), and provides a model for how changes in φ and c/f/cₐ can account for the changes in Δ values we observed.

We found that Δ values of A. confertifolia increased by 2‰ in concordance with increasing salinity (Fig. 2). These Δ values were always greater than 4.4‰; therefore the φ values must be greater than 0.32 (cf. Fig. 3). A 2‰ increase in Δ values, at φ > 0.32, cannot be explained solely by changes in c/f/cₐ given the typical range of c/f/cₐ values for C₄ plants under ambient conditions (0.20-0.40; Pearcy and Ehleringer 1984). To do so would require either extreme leakiness values (φ ≥ 0.6) or an increase of c/f/cₐ with increasing salinity since Δ and c/f/cₐ are positively related when φ > 0.32. Leakiness values greater than 0.6 have
never been reported, and the latter explanation is unlikely since salt stress typically decreases or does not change \( c_i/c_a \) (Long and Baker 1986, Flanagan and Jefferies 1988). A simpler explanation for the change in \( \Delta \) values is that \( \phi \) increases with higher salinity. A 2% increase based on changes in \( \phi \) values can be easily accommodated within the limits of \( c_i/c_a \) found for C\(_4\) plants (Fig. 3). Thus, changes in \( \Delta \) values for \( A. \) confertifolia are more likely due to an increase of \( \phi \) associated with a change in salinity; consequently, the presence of a significant relationship between \( \Delta \) values and EC (Fig. 2).

The trend of increasing \( \Delta \) values with increasing salinity held in all but one site in the two-year study (site 4 in 1991). This deviation could be due simply to the high degree of edaphic variability at site 4; this location had the greatest topographic variability, highest species diversity, and greatest overall variance for soil conductivity and water content (Table 1). Site 4 was also extremely wet in 1991 (near 40% water content at 40–60-cm depth), which may have diluted the salinity of these soils, thereby reducing the salinity experienced by the plants. Without a more detailed study, however, this deviation remains unexplained.

Previous studies have found contrasting patterns of the relationship between \( \Delta \) and salinity. In a laboratory study with 11 C\(_4\) species, Henderson et al. (1992) found that \( \phi \) values were invariable and low, remaining at \( \phi \approx -0.21 \), thereby resulting in a negative relationship between \( \Delta \) and \( c_i/c_a \) (Fig. 3). The small variation they observed in \( \Delta \) values was attributed to changes in \( c_i/c_a \) values. However, in an earlier study with the C\(_4\) monocots Zea mays and Andropogon glomeratus, Bowman et al. (1989) found that \( \Delta \) values of salt-stressed plants were more dramatically influenced by changes in \( c_i/c_a \) than were control plants. The increase of \( \Delta \) values with salinity was explained by a changing relationship between \( \Delta \) and.
and $c_i/c_a$ due to increasing $\phi$ values as the water status of salt-stressed plants declined through the day (Bowman et al. 1989).

Recently, Meinzer et al. (1994) also observed that increasing salinity resulted in increases of $\Delta$ values. Using two sugarcane cultivars, they showed that change in $\Delta$ value could be ascribed to greater $\phi$ values as salinity increased, and that variability of $c_i/c_a$ had much less impact on the increase of $\Delta$ values. In contrast, Walker and Sinclair (1992) reported that $\Delta$ values of two Australian $C_4$ Atriplex species deceased at sites with increased salinity. The $\Delta$ values of these Australian Atriplex leaves were greater than 4.4%o, which could have been achieved only with a bundle sheath leakage greater than 0.32 (Fig. 3). Since the relationship between $\Delta$ and $c_i/c_a$ is positive at $\phi > 0.32$ (Fig. 3), the Walker and Sinclair data suggest that salinity affected a decrease of $c_i/c_a$ and, therefore, a decrease of $\Delta$.

Our findings of a positive correlation between $\Delta$ values of Atriplex confertifolia and salinity are in contrast to findings of Walker and Sinclair (1992). Our observations, like those of Bowman et al. (1989) and Meinzer et al. (1994), suggest that changes in leaf carbon isotope discrimination result from an increased bundle sheath leakage when plants are exposed to a salinity stress. The mechanism of change in $\phi$ values is likely to be associated with physical changes in the bundle sheath permeability to $CO_2$ (or to $HCO_3^-$) and/or biochemical changes in the coupling of Rubisco and PEPC activity. Such biochemical changes due to salinity have been previously found. Guy and Reid (1986) have shown that salinity may reduce Rubisco activity in $C_3$ plants without a concomitant decrease in PEPC activity. Increased salinity (NaCl) has also been shown to increase PEPC activity in some $C_4$ halophytes (Shomer-Ilan et al. 1985). Any such increase in the activities of $C_4$ carboxylation enzymes relative to those of $C_3$ carboxylation enzymes in $C_4$ plants should increase $\phi$ values (Peisker and Henderson 1992). Thus, under natural conditions it appears that salinity could increase $\Delta$ values of A. confertifolia by influencing an increase in $\phi$ values.

The relationship between salt stress and $\phi$ of $C_4$ plants may be species specific or even population specific and may account for discrepancies among different studies of $\Delta$ values in $C_4$ plants. For example, there is high variability among previous studies of carbon isotope discrimination in Atriplex confertifolia; mean $\Delta$ values range from 4.4%o (Marino et al. 1992) to 6.9%o (Troughton et al. 1974). Yet, each of these observations is consistent with the notion that $\phi$ values exceed 0.32 and are therefore high compared to nonhalophytic $C_4$ species (Henderson et al. 1992).

In the present study we have shown that salinity may be one factor that significantly influences variation of $\Delta$ values in $C_4$ plants, most likely through an effect on bundle sheath leakiness. While variation in $\Delta$ values of $C_4$ plants may provide new insights into plant-salinity dynamics along environmental gradients, results also suggest that caution is necessary when using $\Delta$ values of $C_4$ plants to interpret historical changes in atmospheric $CO_2$ concentrations and $^{13}C$ values, as has been proposed by Marino et al. (1992).

ACKNOWLEDGMENTS

We thank University of Utah students in 1991 and 1992 Plant Ecology classes for assistance in sample collection, Craig Cook for assistance in carbon isotope analyses, and Dr. David Williams for salinity analyses comparisons. Dr. Williams and two anonymous reviewers also provided helpful comments on a previous version of this manuscript.
