Abstract—This paper presents a framework for the analysis of mutually-coupled antennas in a multiple-input multiple-output system. The approach uses network theory to formulate the transfer matrix relating the signals input to the transmit antennas to the signals at the output of the receiver front end. This transfer function includes the coupled transmit and receive antennas, the multipath propagation channel, the receiver matching network, and a realistic noise model for the receive amplifiers. Application of the formulation to coupled dipole antennas characterized using full-wave electromagnetic analysis illustrates the performance gains possible from matching the coupled antenna/receive amplifier subsystem for minimum noise figure as compared to matching for maximum signal power transfer.

Index Terms—Amplifier noise, multiple-input multiple-output (MIMO) systems, mutual coupling.

I. INTRODUCTION

MULTIPLE-INPUT multiple-output (MIMO) communication systems use antenna arrays to increase communication capacity by exploiting the spatial properties of a multipath channel [1], [2]. Providing high capacity requires independence of the channel matrix coefficients, a condition generally achieved with wide antenna element spacings. For many subscriber units, such separations are unrealistic, and the resulting antenna mutual coupling [3] can impact communication performance.

Evaluating the impact of antenna mutual coupling on MIMO system performance has generally been approached by examining how the altered radiation patterns change the signal correlation [4], [5] and using this correlation to derive the system capacity [6]–[13]. However, this approach neglects the impact of transmit array coupling on the radiated power as well as the power collection capabilities of the coupled receive array connected through a matching network to the front-end amplifiers. Recent work has demonstrated how these additional considerations can be taken into account [14], [15]. However, in past studies the noise model for the receiver front end is overly simplistic. As a result, the prior observation that the optimal matching network should maximize power transfer is inappropriate for typical amplifier structures with more complex noise characteristics [14].

II. MIMO NETWORK MODEL

Characterizing a complete MIMO communication system requires a model that includes the coupled transmit and receive antenna arrays, the multipath propagation channel, the receiver front-end matching network, and the terminated receiver amplifiers. Fig. 1 shows a block diagram of this system model. In this diagram and throughout the analysis, boldface uppercase and lowercase letters will describe matrices and column vectors, respectively, with $H_{mm}$ denoting the element occupying the $m$th row and $n$th column of the matrix $H$, and $h_{mn}$ representing the $m$th element of the vector $h$. We use scattering parameters (S-parameters) referenced to a real impedance $Z_0$ [16] to describe the signal flow within the network wherein the forward and reverse traveling waves are denoted as $a_T$ and $b_T$, respectively. The flow diagram representation for the receiver network, with the network blocks delineated by dashed lines, appears in Fig. 2.

A. Coupled Arrays and Propagation Channel

We first consider a signal $a_T$ that excites the transmit array consisting of $N_T$ mutually-coupled antenna elements and characterized by an S-matrix $S_{TT}$. The net power flowing into the network is $|a_T|^2 - |b_T|^2$ which, for lossless antennas, equals the instantaneous radiated transmit power $P_{T}\text{inst}$. Since $b_T = S_{TT} a_T$, we have

$$P_{T}\text{inst} = a_T^H (I - S_{TT}^H S_{TT}) a_T$$  \hspace{1cm} (1)

where $\{\cdot\}^H$ is a conjugate transpose. For zero mean signals, the average radiated power is given by

$$F_T = E\left\{P_{T}\text{inst} \right\} = \text{Tr}(R_T A)$$  \hspace{1cm} (2)

where $R_T = E\{a_T a_T^H\}$. $E\{\cdot\}$ denotes an expectation, and $\text{Tr}(\cdot)$ is the trace operation. The effect of this transmitted power
relation on the formulation of the capacity will be addressed in Section III.

The radiation pattern for the \( n \)th element of the transmit array for a unit driving current and all other elements in the array terminated in an open-circuit is denoted as \( e_{Tn}(\theta, \phi) \), where \( (\theta, \phi) \) represent the angular spherical coordinates referenced to the transmit array origin. The two elements of the column vector represent the \( \hat{t} \) and \( \hat{\phi} \) polarizations. The total transmitted field is then

\[
e_T(\theta, \phi) = \sum_{n=1}^{N_T} e_{Tn}(\theta, \phi) i_{Tn} = E_T(\theta, \phi) i_T
\]

where \( i_{Tn} \) is the excitation current on the \( n \)th antenna and \( e_{Tn}(\theta, \phi) \) is the \( n \)th column of the \( 2 \times N_T \) matrix \( E_T(\theta, \phi) \).

We assume that the propagation channel between the transmit and receive arrays consists of a set of \( L \) plane waves, with the \( \ell \)th wave characterized by a complex voltage gain \( \beta_\ell \), angle of departure (AOD) \( (\theta_T\ell, \phi_T\ell) \), and angle of arrival (AOA) \( (\theta_R\ell, \phi_R\ell) \). We also assume that each plane wave undergoes a polarization transformation due to scattering that can be expressed as the unitary matrix

\[
P_\ell = \begin{bmatrix} p_{\ell \theta \theta} & p_{\ell \theta \phi} \\ p_{\ell \phi \theta} & p_{\ell \phi \phi} \end{bmatrix}.
\]

Finally, we represent the radiation pattern of the \( n \)th coupled receive element \( (1 \leq m \leq N_R) \) referenced to the receiver coordinate origin as \( e_{Rm}(\theta, \phi) \). The open circuit voltage on the \( n \)th receive element is then given as

\[
v_{Rm} = \sum_{\ell=1}^{L} e_{Rm}^T(\theta_R\ell, \phi_R\ell) \beta_\ell P_\ell \sum_{n=1}^{N_T} e_{Tn}(\theta_T\ell, \phi_T\ell) i_{Tn} = \sum_{n=1}^{N_T} e_{Tn}^T(\theta_T\ell, \phi_T\ell) \beta_\ell P_\ell e_{Rm}(\theta_R\ell, \phi_R\ell) i_{Tn} / (2Z_0 h_{mn})
\]

where \( {}^T \) is a matrix transpose and the term \( 2Z_0 \) is isolated for later convenience. The vector of received open-circuit voltages at the antenna terminals is then

\[
v_R = 2Z_0 H i_T.
\]

B. Receive Antenna Port Output Signal

We are now poised to formulate an expression for the traveling wave delivered by the receive antenna terminals to a set of independent loads of resistance \( Z_0 \). Denoting this wave as \( b_S \), the antenna port signals for a general termination are related according to

\[
a_1 = b_S + S_{RR} b_1
\]

where we have used the notation of Figs. 1 and 2. For an open-circuit termination \( (a_1 = b_1) \), this yields

\[
b_S = (I - S_{RR}) a_1
\]

where \( I \) represents the identity matrix. Furthermore, the voltage at the open-circuit antenna terminals can be represented by \( v_R = Z_0^{-1/2} (\mathbf{a}_1 + \mathbf{b}_1) = 2Z_0^{1/2} a_1 \). Equating this result to (6) and substitution into (8) leads to

\[
b_S = Z_0^{1/2} (I - S_{RR}) H i_T.
\]

Finally, since the transmit current can be expressed as \( i_T = Z_0^{-1/2} (\mathbf{a}_T - \mathbf{b}_T) = Z_0^{-1/2} (I - S_{TT}) \mathbf{a}_T \), we obtain

\[
b_S = (I - S_{RR}) H (I - S_{TT}) \mathbf{a}_T.
\]

C. Matching Network Output Signal

Given the multiport nature of the receiving system, the matching network will be represented using a block matrix S-parameter description, or

\[
S_M = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix}
\]

where 1 and 2 refer to input and output ports, respectively. With this notation, the signal \( b_S \) at the matching network output can be determined using network theory. To begin, we use (7) with \( b_1 = S_{11} a_1 + S_{12} a_2 \) to obtain

\[
a_1 = (I - S_{RR} S_{11})^{-1} (b_S + S_{RR} S_{12} a_2).
\]
Since \( b_2 = S_{21}a_1 + S_{22}b_2 \) we have

\[
b_2 = S_{21}(I - S_{RR}S_{11})^{-1}b_S + \left[ S_{22} + S_{21}(I - S_{RR}S_{11})^{-1}S_{RR}S_{12} \right] \frac{a_2}{\Gamma_3} \tag{13}
\]

where we have used \( \Gamma_0 \) to represent the reflection coefficient at the matching network output (see Fig. 1).

### D. Noisy Amplifier Output Signal

The added complication considered in this paper is the noise model associated with practical high-frequency transistor based amplifiers. To maintain tractability in the analysis, we will consider amplifier topologies that can be described by input-output S-parameters and standard noise parameters. This data can be readily obtained from manufacturer specifications on transistors designed for low-noise amplifier applications [17].

For the equivalent model adopted in this work, the \( n \)th noisy amplifier injects forward and reverse traveling noise waves \( a_{\eta,m} \) and \( b_{\eta,m} \), respectively, at the amplifier input [18]. Using the notation of Fig. 2, the amplifier signal-plus-noise output waves are of the form

\[
a_L = S_{A,12}b_L + S_{A,22}b_L - S_{A,21}b_{\eta} + a_{\eta} \tag{14}
\]

\[
a_L = S_{A,21}b_L + S_{A,22}b_L - S_{A,21}b_{\eta} \tag{15}
\]

where the subscript "A" denotes the S-parameters of the amplifiers. It is the introduction of the reverse traveling noise wave \( b_{\eta} \) that significantly alters this analysis relative to prior work and that generally leads to different conclusions regarding the impact of the matching network and the optimal achievable performance.

Inserting (14) with \( b_L = \Gamma_L a_L \) into (13) leads to

\[
b_2 = (I - \Gamma_0S_{A,11})^{-1} \left[ S_{21}(I - S_{RR}S_{11})^{-1}b_S + \Gamma_0(b_{\eta} - S_{A,11}a_{\eta} + S_{A,12}\Gamma_L a_L) \right]. \tag{16}
\]

Since \( a_L = S_{A,21}(b_2 - a_{\eta}) + S_{A,22}\Gamma_L a_L \), we obtain

\[
a_L = (I - S_{RR}\Gamma_L)^{-1}S_{A,21}(b_2 - a_{\eta}). \tag{17}
\]

Substituting (16) into (17) and simplifying and subsequently using the fact that the voltage across the load is \( v_L = Z_0^{1/2}(I + \Gamma_L)a_L \) leads to the expression

\[
v_L = Q[S_{21}(I - S_{RR}S_{11})^{-1}b_S + \Gamma_0b_{\eta} - a_{\eta}] \tag{18}
\]

where

\[
Q = Z_0^{1/2}(I + \Gamma_L) \left[ (I - \Gamma_0S_{A,11})S_{A,21}^{-1}(I - S_{A,22}\Gamma_L) - \Gamma_0S_{A,12}\Gamma_L \right]^{-1} \tag{19}
\]

Finally, using the expression in (10) leads to the final form of the load voltage

\[
v_L = Q(GS_{RT}a_T + \Gamma_0b_{\eta} - a_{\eta}). \tag{20}
\]

### E. Matching Network Specification

Practical amplifier design involves specifying an amplifier performance goal and synthesizing the source and load terminations that achieve this goal. Signal amplifiers are typically designed to provide minimum noise figure, optimal power gain, or some compromise between the two [17]. Our main concern in this analysis, therefore, is to define a desired value of \( \Gamma_0 \), which is the source termination seen by the amplifier, and use this value to determine the sub-blocks \( S_{ij} \) of the matching network.

We will restrict our discussion to lossless matching networks that ideally have unity noise figures and are characterized by unitary S-matrices. We can take the singular value decomposition (SVD) of the sub-blocks \( S_{ij} = U_{ij}A_{ij}^{1/2}V_{ij}^H \) in (11), where \( U_{ij} \) and \( V_{ij} \) are unitary matrices of singular vectors and \( A_{ij}^{1/2} \) is a diagonal matrix of real singular values. Then, as detailed in the Appendix, relationships exist among the sub-block singular vectors and values, leading to the forms

\[
S_{11} = U_{11}A_{11}^{1/2}V_{11}^H
\]

\[
S_{12} = -U_{12}\Theta (I - A_{11})^{1/2}V_{12}^H
\]

\[
S_{21} = U_{22}\Theta (I - A_{11})^{1/2}V_{11}^H
\]

\[
S_{22} = U_{22}A_{11}^{1/2}V_{12}^H \tag{21}
\]

where \( \Theta \) is a diagonal phase shift matrix with arbitrary complex elements of unit magnitude.

Given this framework, assume that a desired value of \( \Gamma_0 \) has been provided. Using the form for \( \Gamma_0 \) in (13) coupled with the expressions in (21) leads to

\[
\Gamma_0 = U_0A_0^{1/2}V_0^H
\]

\[
= U_{22}\left[ A_{11}^{1/2} - (I - A_{11})^{1/2}\Theta (I - A_{11})^{1/2} \right]V_{12}^H \tag{22}
\]

\[
T = \Theta V_{11}^H \left( I - S_{RR}U_{11}A_{11}^{1/2}V_{11}^H \right)^{-1}S_{RR}U_{11}\Theta^H, \tag{23}
\]

where the first equality is the SVD of \( \Gamma_0 \). We have flexibility in choosing the singular vectors of \( U_{ii} \) and \( V_{ii} \), \( i \in 1, 2 \), and therefore will choose representations that lead to mathematical simplicity. First, we see that if \( S_{RR} = U_{RR}A_{RR}^{1/2}V_{RR}^H \), then by choosing \( U_{11} = V_{RR} \) and \( V_{11} = U_{RR} \) we obtain

\[
T = \left( I - A_{RR}^{1/2}A_{11}^{1/2} \right)^{-1}A_{RR}^{1/2} \tag{24}
\]

which is diagonal. If we further choose \( U_{22} = U_0 \) and \( V_{22} = V_0 \), we can solve (22) to obtain

\[
A_{11}^{1/2} = \left( A_{0}^{1/2} + A_{RR}^{1/2} \right) \left( I + A_{0}^{1/2}A_{RR}^{1/2} \right)^{-1}. \tag{25}
\]
The matrix $\Theta$ is arbitrary for achieving the design goal provided it is diagonal with complex entries of unit magnitude, and we therefore use $\Theta = jI$.

We assume uncoupled amplifiers ($S_{Ai,j}$ and $\Gamma_L$ are diagonal), so that typical design goals are achieved for diagonal $\Gamma_0$. If $\Gamma_{\text{opt}}$ and $\Gamma_{MSS}$ represent the (scalar) source reflection coefficient for achieving amplifier minimum noise figure and maximum power gain [17], respectively, then achieving these goals are accomplished by setting $\Gamma_0 = \Gamma_{\text{opt}}I$ and $\Gamma_0 = \Gamma_{MSS}I$. Since MIMO capacity depends on signal-to-noise ratio (SNR), we expect a design for minimum noise figure to outperform one for maximum power gain.

To achieve diagonal $\Gamma_0$, the matching network must be coupled to “undo” the coupling created by the antenna, and it therefore acts as an array combining network as well as an impedance transforming network. To explore the implication of this observation, let $e_R(\theta, \phi)$ represent the $2 \times N_R$ matrix with $m$th column $e_{Rm}(\theta, \phi)$. Then, the matrix of effective radiation patterns observed at the matching network output ports can be constructed as

$$ E_R^T(\theta, \phi) = \frac{1}{2\gamma_0} G(I - S_{RR})E_R^H(\theta, \phi). \quad (26) $$

Then, following the development in Section II, we operate the array as a radiator with transmitted field $e_R(\theta, \phi) = E_R(\theta, \phi)i_R$ and total transmitted power

$$ P_{\text{trans}}^m = \frac{1}{2\gamma_0} \int e_R^H(\theta, \phi)e_R^T(\theta, \phi)d\Omega \quad (27) $$

where $\gamma_0$ is the free-space impedance and $\Omega$ represents solid angle. Equating this expression to the radiated power computed using circuit theory (see (1)) yields

$$ (I - S_{RR})\int E_R^T(\theta, \phi)E_R^H(\theta, \phi)d\Omega (I - S_{RR}^H) = 2\gamma_0 Z_0 \left(I - S_{RR}S_{RR}^H\right) \quad (28) $$

where we have used that $i_R = Z_0^{-1/2}(I - S_{RR})b_1$ and $S_{RR}^H = S_{RR}$ by reciprocity.

Using these results with the matching network SVD relationships, it can be readily shown that the matrix

$$ C = \int E_2^T(\theta, \phi)E_2^H(\theta, \phi)d\Omega \quad (29) $$

is diagonal provided that $\Gamma_0$ and therefore $U_0$ are diagonal, which means that the effective radiation patterns seen at the matching network output are orthogonal. This result indicates that 1) the coupled antennas terminated with this matching network maintain unit radiation efficiency as demonstrated in [19], and 2) these virtual radiation patterns provide zero correlation in a propagation environment with full angle spread [4]. Because these patterns are formed by the coupling in the antennas and matching network before injection of the amplifier noise, the system can provide higher MIMO capacity than obtainable from uncoupled antennas without this network.

Finally, since designing coupled matching networks is highly complex, it is common to instead assume that the coupled antenna impedance can be adequately represented using only the diagonal elements of the full impedance matrix $Z_{RR}$ to obtain $Z_{RR}$ and computing a diagonal $S_{RR}$ with elements $S_{RR,ii} = (Z_{RR,ii} - Z_0)/(Z_{RR,ii} + Z_0)$. This value of $S_{RR}$ is then used in place of $S_{RR}$ to specify an uncoupled matching network as outlined above. However, when analyzing the performance of such a match, the nondiagonal form of $S_{RR}$ must be used in (20).

### III. COUPLED SYSTEM CAPACITY

We will use capacity as a metric for comparing the performance of MIMO systems with different coupling levels and matching networks. This capacity is derived from the mutual information which, for the signal in (20) where both the transmit signal $a_T$ and noise are drawn from zero-mean complex Gaussian distributions, assumes the form

$$ I(v_L,a_T) = \log_2 |R_L| - \log_2 |R_N| \quad (30) $$

where $R_L = E\{v_Lv_L^H\}$ is the total voltage covariance and $R_N$ is the noise covariance. We will construct each covariance matrix separately.

#### A. Noise Covariance

For the $m$th amplifier, the statistics of the noise waves $\eta_{\gamma,m}$ and $b_{\eta,m}$ can be represented in terms of effective noise temperatures ($T_{\alpha,m}, T_{\beta,m}, T_{\gamma,m} = T_{\gamma,m}e^{\phi_{\gamma,m}}$) which are readily computed from other noise parameters [18]. If we assume identical amplifiers ($T_{\alpha,m} = T_{\alpha}$, etc.) and that the noise in each amplifier is statistically uncorrelated with that of all other amplifiers, then the noise satisfies

$$ E\{a_\eta b_\eta^H\} = k_B T_{\alpha} B I $$
$$ E\{b_\eta b_\eta^H\} = k_B T_{\beta} B I $$
$$ E\{a_\eta b_\eta^H\} = k_B T_{\gamma} B I \quad (31) $$

where $k_B$ is the Boltzmann constant and $B$ is the system noise power bandwidth.

Using these results in conjunction with (20), the noise covariance can be expressed as

$$ R_N = Q\eta Q^H \quad (32) $$
$$ R_\eta = E\{(\Gamma_{\eta})b_\eta - a_\eta)(\Gamma_{\eta}b_\eta - a_\eta)^H\} = k_B B \left[T_{\alpha}I + T_{\beta} \Gamma_{0} \Gamma_{0}^H - T_{\gamma} \Gamma_{0} - T_{\gamma} \Gamma_{0}^H\right]_{T_{\alpha}T_{\alpha}} \quad (33) $$

where we have factored out the constant $T_{\alpha}$ from $R_{\eta\eta}$ so that the structure of $R_{\eta\eta}$ is a function only of the relative values $T_{\beta}/T_{\alpha}$ and $T_{\gamma}/T_{\alpha}$. Using this representation, the absolute noise value controlled by $k_B B T_{\alpha}$ can be specified based on a desired SNR level.
B. Capacity

The matrix $R_L$ represents the covariance of the received signal plus noise. Using the independence of the signal and noise waves, this matrix may be expressed as

$$R_L = Q \left[ G S_R T R_T S_{R}^{H} G^H + R_n \right] Q^H \quad (34)$$

where $R_T$ was introduced in (2). Using this result and (33), the mutual information in (30) becomes

$$I(v_L, a_T) = \log_2 \left| \frac{G S_R T R_T S_{R}^{H} G^H + R_n}{[R_n]} \right| \quad (35)$$

Finally, if we compute the eigenvalue decomposition (EED) $R_{nc} = \xi_n A_n \xi_n^H$ where $\xi_n$ is unitary, then the mutual information expression becomes

$$I(v_L, a_T) = \log_2 \left| \frac{Y R_T Y^H}{k_B B T_o} + I \right| \quad (36)$$

where $Y = A_n^{-1/2} \xi_n^H G S_R T$. The capacity results when the transmit covariance matrix $R_T$ is specified according to the water-filling solution, with the total transmit power limited according to $\text{Tr}(R_T A) \leq P_T$ as derived in (2). Because this power constraint is a departure from the typical constraint $\text{Tr}(R_T^2) \leq P_T$, the water-filling procedure must be modified, as detailed in [14], [20].

IV. COMPUTATIONAL EXAMPLES

To demonstrate application of the analysis framework developed in this paper and to illustrate the impact of antenna coupling and amplifier matching on MIMO system capacity, we use a model problem consisting of two half-wave dipoles at transmit and receive. The simplicity of this problem allows us to accurately characterize the coupled antennas and draw conclusions concerning the system operation.

A. Antenna Electromagnetic Characterization

While closed-form expressions for coupled dipole impedance matrices exist for reasonable antenna spacings, expressions for the patterns do not, motivating the use of full-wave electromagnetic solutions. Furthermore, simple thin-wire simulations assume that the current is independent of azimuthal angle around the wire, an assumption that is violated for very closely-spaced dipoles [21]–[23]. Since in this work it is desired to characterize the coupled antennas as the spacing is reduced to zero, we have chosen to use the finite-difference time-domain (FDTD) method [24], [25] to perform detailed simulations that return both S-parameter and radiation pattern descriptions for the dipole antennas. In this analysis, the $\alpha$-oriented half-wave (total-length) dipoles with wire radius $0.01\lambda$ and separated by a distance $\delta$ are located at the center of the computational domain. Because we are considering narrowband systems, single-frequency antenna excitation is used. The FDTD grid uses 80 cells per wavelength in the $\alpha$ direction and 200 cells per wavelength in the $x$ and $y$ directions. This finer resolution is required to adequately model the current variation as a function of azimuthal angle on the finite-radius wire for close antenna spacings. Because of the fine grid resolution, a relatively small buffer region of only a quarter wavelength (to minimize simulation memory) is placed between the antennas and the terminating 8-cell perfectly matched layer (PML) absorbing boundary condition (ABC). The impact of this small buffer region was investigated previously and shown to produce fractional errors below $10^{-4}$ relative to the results obtained for a half-wavelength thick buffer [14], [20].

B. Receive Amplifiers

The transistor used as the foundation for the amplifier in this work is a BJT taken from a Hewlett-Packard Application Note [26]. At a collector-emitter bias voltage of 10 V, collector current of 4 mA, frequency of 4 GHz, and reference impedance of $Z_0 = 50 \Omega$, the S-parameters and noise parameters are given as

$$S_{11} = 0.552 \angle 169^\circ \quad S_{12} = 0.049 \angle 23^\circ$$
$$S_{21} = 1.68 \angle 26^\circ \quad S_{22} = 0.839 \angle -67^\circ$$
$$F_{\text{min}} = 2.5 \, \text{dB} \quad \Gamma_{\text{opt}} = 0.475 \angle 16^\circ$$
$$R_n = 3.5 \, \Omega$$

where $F_{\text{min}}$, $\Gamma_{\text{opt}}$, and $R_n$ represent the minimum noise figure, optimal source termination for noise figure, and effective noise resistance, respectively. These parameters are converted to the effective noise temperatures $T_{\alpha}$, $T_{\beta}$, and $T_{\Gamma}$ using standard techniques.

C. Capacity Results

We now explore the capacity of the model system under different matching goals. In these computations, 5,000 random realizations of a path-based, clustered channel model [27] are generated to create a set of transfer matrices $H$ as in (5). Details on the implementation of this model, including the parameters used to model an indoor propagation environment, can be found in [28]. For each realization, we place single dipoles in the transmit and receive spaces and create a lossless receive matching network with $S_{11} = S_{RR}^T$ so that $\Gamma_0 = 0$ (all terms are scalars). We then can simplify the single-input single-output (SISO) SNR as

$$\text{SNR}_S = \frac{|S_{RT}|^2}{1 - |S_{RR}|^2} \frac{P_T}{k_B B T_o} \quad (38)$$

where $P_T$ is the total transmit power. This SNR value is then averaged by moving each dipole in 0.1\lambda steps over a linear range of 1.5\lambda. For a given transmit power, the value of $k_B B T_o$ can be computed to achieve an average SISO SNR (20 dB in this work) for the channel realization.

We next construct the matching network to achieve the specified design goal for each transmit/receive dipole spacing, as outlined in Section II-E. For each configuration, we compute the capacity averaged over the 5,000 channel matrices $H$ with the corresponding noise power levels $k_B B T_o$. The transmit array spacing is fixed at 0.5\lambda. In all plots, we use the abbreviations “NF” and “SI” to indicate matching for minimum noise figure or matching based on the self-impedance (diagonal $S_{RR}$), respectively. We also use “NC” to indicate that coupling is neglected at the receiver. For all cases, we use the same coupled transmit configuration to facilitate meaningful comparison of
the results. Propagation is confined to the horizontal plane such that $\varphi_{TL} = \phi_{RL} = \pi/2$. Since the dipoles and resulting currents are $\varphi$-oriented, only the $\theta$ polarization is required in the channel description in (5). For general antenna geometries that allow currents to flow in other directions, both polarizations should be included in the model.

Fig. 3 plots the capacity as a function of receive dipole spacing for matching networks that achieve minimum noise figure and maximum power gain. Results for a coupled match and a simpler self-impedance match as well as for no receiver coupling are included. We first observe that the match achieving minimum amplifier noise figure (noise figure of $F = F_{\text{min}} = 2.5$ dB) produces notably higher capacity than the match providing maximum power transfer which generates a much higher noise figure of $F = 7.2$ dB. This result is intuitive, since ultimately capacity depends on SNR as opposed to absolute signal strength. However, obtaining this result from simulation is enabled by the improved noise model implemented in this work. We also observe that for close antenna spacings with high coupling, the shortcomings of the self-impedance match are evident. However, once the spacing reaches approximately $d = \lambda/4$, this match provides near optimal performance.

We also observe from Fig. 3 that for small antenna spacings, coupled dipoles can have a higher capacity than uncoupled ones. This stems from the orthogonal radiation patterns observed at the matching network output as discussed in Section II-E. To explore this phenomenon further, we take the EED $A = \xi_A \Lambda_A \xi_A^H$ and, following the developments in [14], [20], construct the effective channel

$$\mathbf{H}_E = \Lambda_\eta^{-1/2} \xi_\eta^H \mathbf{G} S_{RT} \xi_A \Lambda_A^{-1/2}.$$  \hfill (39)

Then, we define $\sigma_E$ as the ratio of the largest to smallest singular values of $\mathbf{H}_E$, a metric that represents the relative quality of the two effective spatial channels. Fig. 4 plots this quantity averaged over the Monte Carlo channel realizations as a function of receive antenna spacing. As can be seen, the orthogonal radiation patterns of the properly-terminated coupled dipoles tend to more effectively equalize the quality of the two spatial channels (smaller $\sigma_E$), which increases MIMO capacity.

A variety of different conclusions concerning the relative performance of uncoupled and coupled antennas have appeared in recent literature. While many studies have demonstrated that coupling increases capacity [6]–[12], others have suggested that this is not the case [13]. First, we point out that none of these prior results have been generated using the model detail included here. Second, this performance enhancement requires an appropriate coupled matching network, which is impractical for most applications and therefore not considered in prior studies. In fact, we have already observed that a more practical self-impedance match does not provide this benefit. Third, a notable recent study has demonstrated that packing an increasing number of dipoles into a linear array of a given aperture size leads to an increasing MIMO capacity unless coupling is included in the analysis [29]. This conclusion should not be viewed as inconsistent with the results included here, since in that case the number of dipoles is varied as the antenna aperture is fixed, while in this case the number of dipoles is fixed while the aperture is varied.

Because of the dependence of capacity on SNR, it is intriguing to consider the match achieving $\mathbf{G}_0 = \mathbf{0}$ which removes the noise term $\mathbf{F}_0 \mathbf{b}_\eta$ from (18) and for this device generates a noise figure of $F = 3$ dB (close to the minimum of $F_{\text{min}} = 2.5$ dB). Fig. 5 compares the capacity of the system using this matching network with that obtained using the other matching criteria. As expected, for this device the performance for $\mathbf{G}_0 = \mathbf{0}$ is very close to that obtained for a match achieving minimal noise figure.

V. CONCLUSION

This paper has outlined a procedure for analyzing capacity performance of MIMO systems with mutually-coupled antenna arrays. The formulation includes a realistic noise model for the
receiving amplifiers and facilitates a careful examination of the system end-to-end performance. The framework also allows specification of the matching network transfer properties to achieve different design goals and includes a radiated power specification of the matching network transfer properties to system end-to-end performance. The framework also allows antennas with matching networks that achieve minimum noise figure, maximum amplifier transistor illustrate the performance differences of superior to matching for maximum power transfer.

**APPENDIX**

Lossless matching networks are characterized by unitary S-matrices such that \( S_M^H S_M = I \). Using the representation in (11) and substituting the SVD of the sub-blocks \( S_{ij} = U_{ij} A_{ij}^{1/2} V_{ij}^H \) into the lossless constraint yields the relations

\[
V_{ij} \Theta_{ij} = V_{jj}, \quad A_{ij} = I - A_{jj} \quad i \neq j \tag{40}
\]

where \( \Theta_{ij} \) is a diagonal matrix with unit-magnitude entries. This operation also produces the condition

\[
A_{11}^{1/2} U_{11}^H U_{12} (I - A_{22})^{1/2} \Theta_{12} = -\Theta_{12}^H (I - A_{11})^{1/2} U_{21}^H U_{22} A_{22}^{1/2}. \tag{41}
\]

There is an entire family of matching networks that satisfy these conditions. Since we are only interested in finding one lossless matching network that achieves specified design goals, we can further specify the singular vectors/values. In this spirit, we choose \( U_{12} = U_{11} \) and \( U_{21} = U_{22} \). Then, according to (41) we obtain \( \Theta_{21} = -\Theta_{12}^H \) and \( A_{22} = A_{11} \). The sub-blocks of \( S_M \) can then be expressed as in (21).
