A mathematical model for GHG from SB-MBR: calibration by an innovative protocol

Mannina Giorgio², Alida Cosenza²
²Dipartimento di Ingegneria Civile, Ambientale, Aerospaziale, dei Materiali, Università di Palermo, Viale delle Scienze, Ed.8, 90100, Palermo, Italy (e-mail:giorgio.mannina@unipa.it; alida.cosenza@unipa.it)

Abstract: A mathematical model to quantify greenhouse gases (GHG) (carbon dioxide, CO₂ and nitrous oxide, N₂O) for a membrane bioreactor (MBR) is presented. The model has been applied to a pilot plant with a pre-denitrification MBR scheme. The pilot plant was cyclically filled with real saline wastewater according to the fill-draw-batch operation. The model was calibrated by adopting a specific protocol based on extensive field dataset. Standardised Regression Coefficient (SRC) method was adopted to select the most influential model factors to be calibrated. Results related to SRC method show that among the important model factors a key role is played by the half saturation coefficients related with the nitrogen removal processes ($K_{N2O}$, $K_{NO}$) and by the model factors affecting the oxygen transfer rate in the aerobic and MBR tank ($k_{a,2}$ and $k_{a,3}$). In terms of uncertainty, it was found that for the gaseous model outputs ($SGHGN2O,1$ and $SGHGN2O,2$) only the 7% and the 12% of the measured data lays outside the bands showing an accurate model prediction in case a wide data set is available.

Keywords: Uncertainty; greenhouse gases; wastewater; membrane.

1 INTRODUCTION

Greenhouse gases (CO₂, N₂O and CH₄) can be directly and indirectly produced by wastewater treatment plants (WWTPs). Direct emissions are mainly debited to the biological processes (emissions of CO₂ from microbial respiration, N₂O from nitrification and denitrification, and CH₄ from anaerobic digestion). Indirect emissions are mainly associated with the energy consumption. Among the GHGs produced by WWTPs, N₂O is the most environmentally hazardous due to its strong global warming potential (GWP) (298 higher that CO₂) and its capacity to deplete the stratospheric ozone layer (IPCC, 2013). N₂O can be produced both during nitrification and denitrification. During nitrification, ammonia oxidizing bacteria (AOB) have been recognized as the main contributor of N₂O production (Kampschreur et al., 2007; Yu et al., 2010). Two different pathways are involved during N₂O production by AOB: (i) the reduction of nitrite (NO₂⁻) to N₂O via nitric oxide (NO) (AOB denitrification) (Chandran et al., 2011) and (ii) N₂O as a product of the incomplete oxidation of hydroxylamine (NH₂OH) to NO₂ (Chandran et al., 2011). Several studies have demonstrated that the N₂O production is strongly depending on the plant operating conditions and on the influent wastewater features (Kampschreur et al., 2009; Peng et al., 2015). Therefore, a huge variations of N₂O emissions can be obtained among different WWTPs and inside the same plant due to the different features of the influent wastewater over the day (dynamic conditions). Despite such a statement, the United Nation's Intergovernmental Panel on Climate Change (IPCC) proposes to adopt simple model, often based on simple emission factor, to estimate the amount of N₂O produced by a WWTP. In this way the variability of the N₂O production due to the dynamic operational conditions is completely neglected (Corominas et al., 2012). In order to overcome such a substantial contradiction between the real conditions affecting the N₂O production in a WWTP and the suggestion to estimate their production, over the last years huge efforts have been performed by the scientific community in order to better quantify N₂O (Ni and Yuan, 2015). Several mathematical models have been proposed, tested and compared in literature in order to establish a reliable model (Corominas et al., 2012; Ni et al., 2013; Spérandio et al., 2016). Corominas et al. (2012) demonstrated that the assessment of GHGs by empirical models (based on a single emission factor) can produce erroneous results as the formation of GHGs is not a
linear process. Therefore, mechanistic process-based dynamic models are required to obtain an accurate estimation of GHG emissions. Ni et al. (2013) have compared four mathematical models able to separately describe the N₂O production by means of AOB as the final product of nitrifier denitrification or as a product of incomplete oxidation of hydroxylamine (NH₂OH). By adopting short-term batch experimental data Ni et al. (2013) found that none of the tested models was able to reproduce data. Moreover, the short term data should also be available for a good model calibration/validation (Ni et al., 2013). Very recently, Spérandio et al. (2016) adopted five activated sludge models describing N₂O production by AOB and compared the results to four different long-term process data sets. Differently to previous studies where only short-term data gathered during batch tests were employed, Spérandio et al. (2016) adopted for the first time long term database to calibrate an N₂O models. Each model adopted by Spérandio et al. (2016) considers one of the two known N₂O production pathways by AOB (denitrification pathway and the hydroxylamine oxidation). Similarly, to Ni et al. (2013), Spérandio et al. (2016) found that, despite at least one of the investigated model was able to reproduce the measured data, none of the tested models describe all the N₂O data (obtained in the different systems) with a similar parameter set. To establish a reliable N₂O model, long term dataset and by a detailed knowledge on the parameters describing the microorganisms behaviour are thus needed (Sperandio et al., 2016). Very recently, with the aim to improve the N₂O quantification a new model combining two N₂O emission pathways by AOB was proposed and calibrated (adopting long-term data) by Pocquet et al. (2016) which showed good adaptation between measured and modelled data. Overall, literature shows, that maturity achieved in N₂O modelling has enabled the improvement of site-specific N₂O emissions (Ni and Yuan, 2015). However, despite the useful insights derived by N₂O mathematical models from WWTPs the derived results are likely to be subjected to a high degree of uncertainty (Sweetapple et al., 2013). Thus, the assessment of the uncertainty may improve the calibration process. With this aim the sensitivity and uncertainty analysis could help modeller to identify the key source affecting model outputs (Sweetapple et al., 2013). Despite the usefulness of uncertainty analysis only few studies have been performed in literature (Flores-Alsina et al., 2014; Sweetapple et al., 2013) mainly related to conventional activated sludge (CAS) system. Only recently, Mannina and Cosenza (2015) have presented a detailed uncertainty analysis of a new Activated Sludge Model (ASM2d) Soluble Microbial Product (SMP) – GHG model applied to a membrane bioreactor (MBR) University Cape Town (UCT) pilot plant. Mannina and Cosenza (2015) found that model factors related to the physical processes through the membrane could affect the GHG production. However, the study of Mannina and Cosenza (2015) have the limit of not being supported by GHG measured data.

In order to detail the GHG modelling in MBR plant, in this work a new mathematical model is presented. The mathematical model has been applied to a sequential batch (SB) MBR pilot plant fed with real saline wastewater. The model has been calibrated by adopting a detailed protocol developed in a previous study (Mannina et al., 2011b). A long-term data base (for dissolved and gaseous N₂O), acquired during an extensive gathering campaign, was adopted for the model calibration. Uncertainty analysis has also been performed.

2 MATERIAL AND METHODS

2.1 The mathematical model

The proposed model couples the ASM1 model (Henze et al., 2000) and the N₂O modelling production according to the approach of Hiatt and Grady (2008). The model has the peculiarity of including the SMPs modelling (formation/degradation of both utilisation associated products and biomass associated products) in order to take into account their influence on membrane fouling. The mathematical model is divided into two sub-models: a biological sub-model and a physical sub-model. The physical sub-model simulates the main physical processes through the membrane: rate of sludge attachment and sludge detachment on the membrane surface during suction and backwashing phase, the solid mass deposition on the membrane surface, the thickness of the cake layer and the pore fouling by adopting the resistance in series model. The physical sub-model involves 6 model factors. For sake of conciseness for a detailed description of the physical sub-model the reader is referred to the literature (Mannina et al., 2011a). The biological sub-model involves: 16 biological processes (aerobic and anoxic); 19 state variables, which include dissolved N₂O and CO₂ (S₅NO₂ and SCO₂, respectively) and 68 model factors. In the Appendices A and B, the Gujer Matrix and the process rate equations of the biological model are reported, respectively. The model also includes the stripping
processes for N\textsubscript{2}O and CO\textsubscript{2} in order to evaluate the gaseous N\textsubscript{2}O and CO\textsubscript{2} (S\textsubscript{GHG,N2O} and S\textsubscript{GHG,CO2}). According to the Hiatt and Grady (2008) approach the nitrogen removal process is described as a two steps nitrification and four steps denitrification processes. With this regard the autotrophic biomass is modelled as ammonia-oxidising biomass (X\textsubscript{AOB}) and nitrite oxidising biomass (X\textsubscript{NOB}). In order to model the SMP formation/degradation the aerobic and anoxic hydrolysis processes related both to the UAP (S\textsubscript{UAP}) and BAP (S\textsubscript{BAP}) have been added in the ASM1 (see Appendix B). The rate of the anoxic hydrolysis of S\textsubscript{BAP} is provided in Equation 1.

\[
k_{b,BAP} \cdot \eta_{NOI\textsubscript{HYD}} \left( \frac{K_{O2\textsubscript{HYD}}}{K_{O2\textsubscript{HYD}} + S_{O2}} \right) \left( \frac{S_{NO3}}{K_{NO1\textsubscript{HYD}} + S_{NO3}} \right) \cdot S_{BAP} \cdot X_{H}^{(1)}
\]

Further, the hydrolysis processes of X\textsubscript{s} have also been added in the model.

Detailed description will be provided in the extension version of the manuscript. The biological model takes into account the influence of the salinity both for the autotrophic and heterotrophic biomass according to Park and Marchland (2006). More precisely, the maximum growth rate of both autotrophic and heterotrophic biomass has been reduced of the Is coefficient. This latter coefficient has been evaluated according to the Equation 2.

\[
I^* = \frac{I}{I + \%NaCl}
\]

Where I* represents the inhibition factor evaluated and \%NaCl is the percentage of salinity expressed as NaCl content.

### 2.2 The case study

An SB-MBR pilot plant consisted of two reactors in-series, one anoxic (volume 45 L) and one aerobic (volume 224 L), according to a pre-denitrification scheme (Figure 1) was monitored for three months. The pilot plant was equipped with an hollow fiber membrane module (Zenon Zeeweed, ZW10) installed into a separate aerated compartment (volume 50 L) for the solid liquid separation. An oxygen depletion reactor (ODR) was placed in the recycling line in order to ensure anoxic conditions inside the anoxic reactor despite the intensive aeration in the aerobic tank. The aerobic, anoxic and MBR reactors were equipped with specific covers that guaranteed the gas accumulation in the headspace.

![Figure 1. Layout of the SB-MBR pilot plant](image_url)
concentration) were cyclically fed in, whereas the permeate was extracted at 20 L h\(^{-1}\) (Q\(_{OUT}\)). Each cycle had the duration of 3 hours that were split into 1 hour of biological reaction and 2 hours of MBR filtration. During the biological reaction time the permeate extraction pump was turned out, thus Q\(_{OUT}\) was equal to zero. During the cycle, 80 L h\(^{-1}\) (Q\(_{IN}\)) were continuously pumped from the aerobic to the MBR tank. Furthermore, a recycling activate sludge stream (Q\(_{RAS}\)), equal to 80 L h\(^{-1}\) during the reaction period and to 60 L h\(^{-1}\) (Q\(_{RIT\_Q_{OUT}}\)) during the filtration phase, was recycled from the MBR to the anoxic tank via the ODR tank. The experimental campaign was divided into six phases each characterized by a specific salt concentration from 0 up to 10 g NaCl L\(^{-1}\). The NaCl concentration in the influent was increased at step of 2 g NaCl L\(^{-1}\) on a weekly basis. The Phase VI had a duration of 26 days. During the experimental campaign, gaseous and dissolved N\(_2\)O from the aerobic and anoxic tank were measured by using a Gas Chromatograph (Thermo Scientific™ TRACE GC) equipped with an Electron Capture Detector. Sample were withdrawn during an entire cycle (every 15 min for the gaseous sample and every 60 min for the liquid sample) at fixed salinity. During plant operations, the influent wastewater, the mixed liquor inside the anoxic and aerobic tank and the effluent permeate have been sampled and analyzed for total and volatile suspended solids (TSS and VSS), total chemical oxygen demand (COD\(_{TOT}\)), supernatant COD (COD\(_{SUP}\)), ammonium nitrogen (NH\(_4\)-N), nitrite nitrogen (NO\(_2\)-N), nitrate nitrogen (NO\(_3\)-N), total nitrogen (TN), phosphate (PO\(_4\)-P), total carbon (TC) and inert carbon (IC). Further details can be drawn from previous studies (Mannina et al., 2016b).

2.3 Calibration protocol and uncertainty estimation

Model calibration has been performed by adopting the calibration protocol as proposed by Mannina et al. (2011b). After a first trial and error calibration, the aforementioned protocol takes into account the selection of model factors of being calibrated for the model outputs of interest. Further, important model factors are calibrated on the basis of the measured data. More precisely the protocol takes into account the adoption of the generalized likelihood uncertainty estimation (GLUE) methodology (Beven and Binley, 1992); based on Monte Carlo simulations: a large number of model parameter sets are generated from the multidimensional parameter space, each with random parameter values selected from uniform probability distributions for each parameter in order to explore the whole confidence region. The acceptability of each set is assessed by comparing predicted to observed data throughout a chosen likelihood measure/efficiency. In this study the same likelihood measure as adopted by Mannina et al. (2011b) was used. The standardized regression coefficient (SRC) method has been adopted to select important model factors (1500 simulations were performed to adopt SRC) (Saltelli et al., 2004). The SRC method consists of a Monte Carlo simulation (with random sampling of the model factors) and a multivariate linear regression between the model output and the considered model factors. The absolute value of the standardised regression slopes of the regression (SRC or β) represents the measure of sensitivity. The sign of β indicates if the model factor “i” has positive (+) or negative (-) influence on the considered model output. Regarding the uncertainty analysis, non important parameters are fixed to their default or trial and error calibration value. Further, only the model factors classified as important are considered to be uncertain and varied in the uncertainty range according to a random sampling. The results of the Monte Carlo simulations were interpreted by evaluating the cumulative distribution function (CDF) for each model output. The 5\(^{th}\) and 95\(^{th}\) percentiles were also evaluated.

3 RESULTS AND DISCUSSION

For sake of conciseness in the following sections only the results related to the dissolved and gaseous N\(_2\)O (S\(_{N2O}\) and S\(_{GHG,N2O}\)) model output will be discussed. In detail, results relate to both anoxic (section 1) and aerobic (section 2) tank will be considered.

3.1 Sensitivity analysis

Figure 2 shows the results related to the important model factors at least for one of the model outputs considered: S\(_{N2O,1}\) (a), S\(_{GHG,N2O,1}\) (b), S\(_{N2O,2}\) (c) and S\(_{GHG,N2O,2}\) (d). For the meaning of the symbols reported in Figure 2 the reader is referred to the literature (Mannina and Cosenza, 2015). Among the important model factors, some merit to be discussed in detail. The group of half saturation coefficients (\(k_{N2O}, k_{NO3}, k_{ALK}\)) (related with the S\(_{N2O}\), S\(_{NO3}\) and S\(_{ALK}\)) have a great influence on all the model outputs
considered. Such a result corroborates the literature findings, which indicate an high degree of uncertainty of the half-saturation coefficient related to the nitrogen transformation processes (Sweetapple et al., 2013). Therefore, when possible it is suggested to experimentally quantify these factors. The model factors $\mu_{AUT,AOB}$ and $\mu_{AUT,NOB}$ mostly affect (positively) the $S_{\text{N2O},1}$ and $S_{\text{GHG,N2O},2}$. Such a result shows an indirect effect for $S_{\text{N2O},1}$. Indeed, with the increasing of the autotrophic maximum specific growth rate the availability of nitrate inside the aerobic tank increases with a consequent increase of $S_{\text{N2O},1}$ produced during the denitrification for example due to the scarce availability of substrate. The importance of the factors $\eta_3$ and $\eta_4$ for $S_{\text{GHG,N2O},1}$ is of relevant interest. Indeed, these latter factors control the rate of the heterotrophic anoxic processes on the substrate ($S_{S}$) when $S_{\text{NO2}}$ (nitrite) is reduced to $S_{\text{NO}}$ ($\eta_3$) and when $S_{\text{NO}}$ ($\eta_4$) is reduced into $S_{\text{N2O}}$. Thus, consequently influence the amount of gaseous $\text{N}_2\text{O}$ emitted from the anoxic tank ($S_{\text{GHG,N2O},1}$). The influence of $k_{2,2}$ and $k_{2,3}$ (coefficients for oxygen transfer of the aerobic tank and MBR tank, respectively) have both positive effect on $S_{\text{N2O},1}$. Such a result is mainly debited to the fact that with the increasing of the oxygen concentration inside the aerobic and MBR tanks both the amount of nitrate and dissolved oxygen recycled into the anoxic tank increase. Therefore, the $\text{N}_2\text{O}$ can be also produced due to the AOB contribution inside the anoxic tank (in case the environment become aerobic).

\end{align*}

**Figure 2.** Results related to the SRC application for $S_{\text{N2O},1}$ (a), $S_{\text{GHG,N2O},1}$ (b), $S_{\text{N2O},2}$ (c), $S_{\text{GHG,N2O},2}$ (d) model outputs.

Thus, the role of $k_{2,2}$ and $k_{2,3}$ on $S_{\text{N2O},1}$ is mainly indirect. Indeed, with the increase of $k_{2,2}$ the amount of the available oxygen inside the aerobic tank increases with a consequent complete nitrification. Therefore, the amount of nitrate to be denitrified in the anoxic tank increases; nitrate could not be completely denitrified due to the scarce availability of carbon. On the other hand, with the increase of
the amount of mass oxygen recycled from the MBR to the anoxic tank (through the ODR) increases. The importance of the factors affecting the oxygen transfer rate in the aerated tank suggests that in order to better predict N\textsubscript{2}O emissions of a WWTP a detailed knowledge on the oxygen transfer has to be acquired. Results of Figure 2, shows that the autotrophic salinity inhibition coefficient (I\textsubscript{s,h}) positively influences the N\textsubscript{2}O production inside the aerobic tank. Indeed, several studies have demonstrated that the salinity could promote the N\textsubscript{2}O production during the nitrification (Zhao et al., 2014). It is interesting to note that factors related to the physical model (\alpha and \lambda, representing the stickiness of the biomass particles and the screening parameter, respectively) affect both S\textsubscript{N\textsubscript{2}O,1} (Figure 2). Such a result is mainly debited to the role of the membrane in retaining the substrate that will be or not available for the nitrate denitrification.

### 3.3 Calibrated model

Table 1 summarizes the results related to the model efficiency. By analysing Table 1 one can observe that an acceptable adaption (the efficiency was almost always greater than 0.45; with exception of the model output related to the MBR tank) between measured an modelled data was obtained. The lower efficiency for the model output related to the MBR tank can be likely debited to the lower number of measured data with respect to the other sections.

### 3.2 Uncertainty analysis

In Figure 3 the CDF of calibrated, measured, 5\textsuperscript{th} and 95\textsuperscript{th} percentiles for S\textsubscript{GHG,N\textsubscript{2}O,1} (a), S\textsubscript{N\textsubscript{2}O,1} (b), S\textsubscript{GHG,N\textsubscript{2}O,2} (c) and S\textsubscript{N\textsubscript{2}O,2} (d) are reported. By analysing data reported in Figure 3 one can observe that the uncertainty band width (as average difference between 95\% and 5\% percentile) changes with the model outputs in the different plant sections (e.g., greater for S\textsubscript{GHG,N\textsubscript{2}O,1} and S\textsubscript{N\textsubscript{2}O,2}). Such a result is mainly due to the fact that some model outputs entail different level of complexity in terms of involved phenomena in the different plant sections. Further, the variation of some factors could make more uncertain the N\textsubscript{2}O production in a certain section due to the overlapping effects among different processes. For example the increase of k\textsubscript{2,2} and k\textsubscript{2,3} could make the environment aerobic in a certain time during the cycle inside the anoxic tank. Therefore, both aerobic and anoxic N\textsubscript{2}O formation could occur inside the anoxic tank. By analysing data of Figure 3 it is possible to observe that for the model outputs for which a greater number of measured data was available (S\textsubscript{GHG,N\textsubscript{2}O,1} and S\textsubscript{GHG,N\textsubscript{2}O,2}) a more accurate prediction can be obtained by adopting model. Indeed, for S\textsubscript{GHG,N\textsubscript{2}O,1} and S\textsubscript{GHG,N\textsubscript{2}O,2} only the 7\% and the 12\% of the measured data lays outside the band width. Such a result is of paramount interest, suggesting that long extensive data base are required to set up accurate model and to reduce the model uncertainty associated with the model predictions. Indeed, the 60\% and the 46 \% of the measured data lays...
outside the band width for $S_{\text{N}_2\text{O},1}$ and $S_{\text{N}_2\text{O},2}$, respectively. More precisely, the measured data lower than 0.01 mgN L$^{-1}$ and 0.025 mgN L$^{-1}$ lays outside the band for $S_{\text{N}_2\text{O},1}$ and $S_{\text{N}_2\text{O},2}$, respectively.

![Figure 3.](image)

**Figure 3.** CDF related to the measured data, calibrated model, 5% and 95% percentiles for $S_{\text{GHG,N}_2\text{O},1}$ (a), $S_{\text{N}_2\text{O},1}$ (b), $S_{\text{GHG,N}_2\text{O},2}$ (c) and $S_{\text{N}_2\text{O},2}$ (d).

### 3 CONCLUSIONS

The main conclusions from this study can be drawn:

- An accurate knowledge on the model factors related to the oxygen transfer, in the aerated tanks, and on the half-saturation coefficients related to the nitrogen removal could improve the model predictions. Therefore, lab tests to acquire these data are suggested.
- Factors related to the membrane solid-liquid separation can indirectly affect $N_2O$ production due to their capability to influence the higher or lower availability of the substrate during the denitrification.
- Model outputs for which a greater number of measured data was available ($S_{\text{GHG,N}_2\text{O},1}$ and $S_{\text{GHG,N}_2\text{O},2}$) a more accurate model prediction occurred, thus suggesting that a long term extensive database has to be required for the setting up of an accurate model to predict $N_2O$.
